oxide, SnO_2 , is reduced by potassic cyanide with great facility; while tungstic acid, WO_3 , undergoes no reduction, even when heated with the cyanide at a high temperature. The oxides of tin and tungsten are to be heated in a porcelain crucible with three or four times their weight of commercial potassic cyanide, previously fused, pulverised, and thoroughly mixed with the two oxides. The mass is kept fused for a short time, when the tin separates in the form of metallic globules, while the tungstic acid unites with the alkali of the potassic cyanide and carbonate present. After cooling, the mass is to be treated with hot water, which dissolves the alkaline tungstate and other salts, and leaves the tin as metal; this is to be separated by filtration, washed, dried, and weighed as stannic oxide, after oxidation in the crucible with nitric acid. The tungstic acid may be estimated by difference, or be precipitated by mercurous nitrate after boiling the solution with nitric acid, to decompose the excess of potassic cyanide present, and then re-dissolving the precipitated tungstic acid by means of an alkali. The author quotes some examples of experiments made by him with this method, from which it appears to be very correct. Tin cannot be separated from molybdenum by this process, because molybdic acid is always more or less reduced to a lower oxide.

Treatment of Gelatinous Precipitates.—T. M. Chatard.—After referring to the inconvenience and loss of time familiar to all chemists which attend the washing of all gelatinous precipitates, the author suggests that the solution containing the substances to be determined is to be simply evaporated to perfect dryness (best on a water-bath) with a small excess of the precipitant, and the gelatinous mass stirred with a rod, until it becomes a perfectly dry powder. The author communicates the results of some experiments made by him according to this plan, from which it appears that the accuracy of the analytical results rather gains than loses by this method.

Precipitation of Antimonous Sulphide from Boiling Solutions.—S. P. Sharples.—In order to obtain the precipitate of antimonous sulphide in a granular state, the author employs the following process:—Into the solution containing, as usual, tartaric and free hydrochloric acid, a current of sulphydric acid gas is to be passed; the liquid being, during the passage of the gas, gradually heated to the boiling-point. The boiling is to be continued for fifteen or twenty minutes, the current of the gas passing, uninterruptedly, until the voluminous sulphide has become a dense granular powder occupying but a small portion of the original volume of the sulphide. The precipitate thus obtained may be washed with great facility, and dried at 200° – 300° . Arsenous sulphide does not become granular and dense under the same conditions. The author incidentally observes that the sulphides of nickel and cobalt, when thrown down from boiling solutions, should be filtered off and washed immediately after precipitation; in this manner, there is no oxidation upon the filter, even during the drying of the precipitate.

Introduction of the Principle of Repetition into Chemical Analysis.—Bryant Godwin.—What the author desires should be done is best elucidated by the instance quoted by him at some length.—When iron is determined by means of potassic permanganate, all the iron is, at the end of the operation, in the form of sesquioxide, while there is also a very small excess of unreduced permanganate. When the solution is boiled for a short time with pure zinc-dust, and rapidly filtered and washed with water (previously boiled to expel air), the iron is left as ferrous oxide, and the process of titration may be repeated a second, and even many more times, until the bulk of the liquid becomes too large to handle. The author quotes the results of a series of analyses made in this way; which serve to show that, with more practice and experience, the principle at least holds good, since, in one case, five repeated titrations gave 14.31 per cent of iron; and, in another case, seven successive titrations gave 14.23 per cent, while the formula required 14.27 per cent.

Pure Scarlet.—W. H. Dall.—The author, in a letter to Professor Silliman, states that, in 1863, while engaged in making anatomical drawings from living microscopic animals, he purchased, among other colours (water colours), a cake (made by Winsor and Newton, of England) stamped "pure scarlet"; it was, indeed, the finest and most vivid scarlet—far superior in brilliancy to any of the various shades of vermilion which are commonly sold. The author further states that he had no occasion to use the colour until 1865, and, later, in 1866 and 1869. The objects coloured with this colour were found to fade very rapidly; and, in one instance, a valuable drawing was lost by the complete fading of this colour, which had been applied for scientific purposes. On examination of the substance, it (the cake of colour) was found to be soluble in iodide of ammonium and hyposulphite of soda; and, with nitrate of silver solution, iodide of silver was produced. The author supposed that the colour was acted upon by hyposulphite of soda, present in the paper; but this supposition is doubtful, considering that three kinds of paper (one of them made expressly for water-colour drawing) gave the same result. Professor Silliman states, in a foot-note, that he tested the small sample of colour sent him, and found it to be mercuric iodide, well known to chemists as very volatile, changing, at a gentle heat, from scarlet to nearly white, and the latter returning again to scarlet by friction. Since this exceedingly attractive pigment is liable to be used by naturalists in valuable drawings, it may not be out of place to call their attention to its ephemeral properties.

Bulletin Mensuel de la Société Chimique de Paris (double number)
September and October, 1870.

From the *procès verbaux* of the two latest meetings held by this Society, we quote the following particulars:—

Researches on Albumen.—Dr. Gautier.—The albumen present in the so-called white of eggs consists of two different modifications of that substance; one of these bodies is coagulated at 63° , the other at

74°; they are present in the white of eggs in the proportion of 1 to 5. The rotatory power of the first is 43°; that of the second, about 26°. White of eggs contains, moreover, a casein-like matter, and lacto-proteine. When white of eggs is treated with water at 15° (that is to say, is kept under water) for six months, in such a manner as to prevent its putrefaction, it becomes partly incoagulable, while the products formed by this reaction differ from those which are formed at 150°, since the pure albumens obtained by dialysis yield, at that temperature, a soluble and insoluble portion, containing—(1) A substance resembling casein; (2) a substance precipitable by acetate of copper, and analogous to hypoxanthine; (3) a residue partly soluble in alcohol, which, by the aid of corrosive sublimate and basic acetate of lead, are split up into various other albumenoid bodies.

Phospho-Platinic Compounds.—Dr. P. Schützenberger.—When the compound $\text{PtCl}_2 \cdot \text{PtCl}_4$ is treated with alcohol, there is formed $\text{Pt}(\text{C}_2\text{H}_5\text{O})_3\text{PtCl}_4$, a crystalline body soluble in alcohol and in dilute hydrochloric acid. This substance plays the part of a diatomic radical, the trioxethyl-phosphoplatine. The different salts of this radical are obtained by means of double decomposition between a silver-salt and the alcoholic solution of the chloride. Baryta converts this chloride into a black compound, which is the hydrate of the radical, which latter is obtained in the shape of a black viscous mass, by the action of zinc upon the alcoholic solution of the chloride. The radical combines with chlorine directly, the result being the reproduction of the chloride. The chloride of trioxamyl-phospho-platine is obtained as the chloride just alluded to, simply by replacing the hydride of amyl for alcohol. The compound $\text{Pt}_2\text{Cl}_2\text{PtCl}_4$ formed by the action of PtCl_2 upon $\text{PtCl}_2 \cdot \text{PtCl}_4$ yields, with water and with alcohol, hexatomic derivatives.

Chlorhydrate of Cyanogen.—Dr. A. Henniger.—The speaker stated, in reference to the fact that MM. Naumann and E. Vogt have proved, recently, that the compound $2\text{C}_2\text{Cl}_2\text{CyH}$, discovered and described by Dr. A. Wurtz, does not exist as a separate and definite chemical body, has been long since known to Dr. Wurtz; and, as a proof thereof, is quoted a phrase from the "Dictionnaire de Chimie Pure et Appliquée," vol. i., p. 1080, where it reads—"Dr. Wurtz had called chlorhydrate of cyanogen a product which he now considers as a mixture, or, at most, an unstable compound of chloride of cyanogen and hydrocyanic acid."

Action of Silver upon Monochlorhydrine.—Dr. Silva states—When monochlorhydrine—

is acted upon by very finely-divided metallic silver at 180°, with the view of withdrawing the chlorine, and also to see whether two molecules of the mono-atomic residue—

will combine to form erythrite, the reaction appears to be such as theory would lead to expect.

Solubility of Oxygen in Molten Silver.—Dr. P. Schützenberger says that he and M. Grange are engaged in making experiments on the solubility of oxygen in molten silver; and he gave a *visd voce* description (not quoted in print) of the apparatus employed.

This number contains, further, the following original papers:—

Preliminary Communication on the Fatty Matters contained in Chyle.—Dr. Dobrosławine.—This portion of the author's labours is devoted to a chemical investigation of the fatty substances present in the chyle taken from the *ductus thoracicus* of cows while the digestion of these animals was in full activity. The chyle, having been dried, was exhausted with ether, by the evaporation of which there was left a brownish-coloured, solid, partly crystalline mass, soluble in warm ether and in boiling alcohol at 95 per cent. The purified fat was found to contain, in 100 parts—Carbon, 75.36; hydrogen, 12.36. When this fatty matter was saponified, by means of an alcoholic solution of caustic potassa, some ammonia was given off. The purified fatty acid was found to yield, on elementary analysis, in 100 parts—Carbon, 75.98; hydrogen, 12.93. Formula, $\text{C}_{14}\text{H}_{26}\text{O}_2$. The author states that, judging from the irregularity of the point of fusion and consolidation, this fatty acid is a mixture of 60 per cent stearic, and 40 per cent palmitic acid. Chyle also contains some oleine.

Spectroscopic Reactions of Sulphur; and on the Flame of Hydrogen.—G. Salet.—In this paper, the continuation of a lengthy memoir on this subject, the author describes some peculiarities of the blue flame of sulphur and some of its compounds. This blue flame is not hotter than red-hot iron, and contains reduced sulphur; but, at the periphery of the flame, very active oxidation takes place, and sulphuric acid is formed. The author describes, at length, an arrangement to prove this fact; and this same arrangement is suitable to prove, by experiment, that the zone of aqueous vapour which envelops the flame of burning hydrogen, contains nitric acid and deutoxide of hydrogen.

Annalen der Physik und Chemie, von Poggendorff, No. 7, 1870.

This number contains the following original papers and memoirs:—

Change which Radiation of Heat Undergoes by the Roughness of the Surface of Bodies.—G. Magnus.—Illustrated by several engravings.

Specific Gravity of Alcohol and of Mixtures of Alcohol and Water.—Dr. E. H. von Baumhauer.—The contents of this paper are

essentially the same as those of the same author's paper quoted in CHEMICAL NEWS, vol. xxii., p. 71.

Passage of Mercury through Glass Capillary Tubes.—E. Warburg.—An algebraico-physical essay, illustrated with woodcuts.

Continued Researches on Liquid Conductors of Electric Currents.—J. W. Müller.—The last instalment of a very exhaustive and lengthy memoir.

Estimation of the Fusion and Solidification Point of Fats and other Substances.—F. Rüdorff.—The main point of interest in this paper is that the author proposes that, instead of taking the fusion-point of such substances as fats, fatty acids, wax, paraffin, and the like, it is preferable to determine accurately the point of solidification of these substances, since that point can be determined with far greater accuracy than the fusing-point.

Electromotive Force Developed by the Contact of Divers Metals.—E. Edlund.

Researches on the Properties of the Images Produced by Photographic Lenses.—Dr. H. Vogel.—Illustrated with a series of engravings.

Velocity of Light while Passing through Quartz.—V. Lang.
Specific Heat of Saline Solutions and Mixtures of Liquids.—A. Willner.

Melting of Lead-Shot Fired against an Iron Target.—E. Hagenbach. Illustrated with diagrams.

Experiment on the Simultaneous Boiling of Two Liquids which are not Miscible.—A. Kundt.—The chief point of interest in this paper, wherein the author gives an account of a series of experiments made with water and benzol, water and oil of cloves, water and sulphide of carbon, is, that two liquids, not miscible with each other when in contact, boil at a lower temperature than when the most volatile of these liquids is brought to ebullition by itself.

Microscopically-Small Tridymite.—F. Zirkel.

Acoustical Attraction and Repulsion.—K. H. Schellbach.

Polytechnisches Journal von Dingler, first number for September, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Experiments to Determine the Value of Various Kinds of Oils Used for Machinery.—H. Fischer.—This paper, chiefly filled with tabulated results of experiments, contains the record of trials of various kinds of oils used for the greasing of machinery, in order to determine their fitness.

Manufacture of Coke from Non-Caking Coals.—E. Vériot and T. Appolt.

Contribution to the History and Statistics of the Manufacture of Mineral Oils, Paraffin, and the Distillation of Brown Coals in Saxony.—R. Jacobi.—The contents of this paper, chiefly of local interest, contain a series of tabulated forms, from which it appears that the industry alluded to is very extensive.

Description of a Process by means of which all Printed Matter, Printed Plates, and Lead-Pencil Drawings may be Readily and Rapidly Copied without any Detriment to the Original.—C. Puscher.—This paper, too lengthy for any useful abstraction, contains the description of a process, and the receipts for making the required preparations, by means of which the object above quoted may be effected; but, judging from the description given, the process is rather a complicated affair.

Extract of Madder for Use in Calico-Printing.—P. Schützenberger.—After referring to the history of the preparation and application of extracts of madder, the author chiefly treats on the use of alizarine direct and without any mordant. This alizarine is that which is obtained from so-called green alizarine (prepared from madder-root), by means of petroleum. The success of the direct application of alizarine depends, first, upon the use of a very pure extract of madder; next upon the use of pure acetate of alumina and a proper solvent for the colouring matter, usually strong acetic acid; and, lastly, upon the simultaneous application of certain substances—preparations of tin, fatty acids, certain salts of lime—all of which serve partly to give a certain hygroscopic action, and also to modify the shade of the colour. Pure alizarine yields a brilliant violet, but it has a reddish hue. Unless purpurine is simultaneously present, alizarine does not yield a good red.

Practical Value of the Continuously-Acting Diffusion Apparatus in Beet-Root Sugar Works.—Dr. O. Cech.

New Method for Analysing Milk.—R. Pribram.—This lengthy memoir is illustrated with woodcuts absolutely required to render the contents of the paper understood.

Preparation to render Lead-Pencil Drawings, Tracings, and Writing, and also Charcoal and Chalk Drawings, Fixed.—W. Wolanek.—The author states, that when the paper containing drawings or writings made with lead pencil or charcoal is painted over, on the reverse side (where no writing or drawing exists) with a moderately-strong solution of bleached shellac in alcohol, the drawings or writings made with lead pencil, &c. become thoroughly fixed, so that they cannot be rubbed off.

Poisoning by Dyeing Aniline Black.—A. Dollfus.—The author states that, while two of his workmen were engaged in dyeing cotton yarn in a hot mixture consisting of aniline, hydrochloric and tartaric acids, sulphuret of copper, chlorate of potassa and water, the men

were suddenly seized with severe headache, difficult respiration, tremor and languor, becoming cold and very weak. Properly administered medical aid restored them to health; but the author cannot well account for these symptoms but by assuming them to be due to the volatilisation of some chloride of arsenic, which may have been formed in consequence of some arsenic having been left in the aniline by careless manufacture; unless, indeed, the symptoms are due to the action of the vapours of aniline itself.

Journal für Praktische Chemie, No. 14, 1870.

This number contains the following original papers and memoirs:—

Some New Sulpho-Salts.—R. Schneider. This paper, the concluding portion of this very lengthy and exhaustive monograph, contains the following chapters:—Sodium platinum-sulpho platinate— $\text{Na}_2\text{S}_2\text{PtCl}_6$, PtCl_2S_2 , PtCl_4S_2 ; Potassium platinum-sulpho stannate; sodium platinum-sulpho stannate; disodium platinum-sulpho platinate; silver platinum-sulpho platinate; thallium platinum-sulpho platinate; copper platinum-sulpho platinate; platinum-sulpho platinate; mercuric platinum-sulpho platinate, with bichloride of mercury; sulpho potassium-sulpho thallium. Of all these salts, the mode of preparation, composition per cent, and formulae are given.

Condition of Chemistry in France.—Prof. H. Kolbe.

On Acridine.—C. Graebe and H. Caro.—The authors discovered, while engaged in purifying crude anthracene, a new substance, which, on account of its biting action when brought into contact with the skin, they have called acridine, a colourless crystalline body, fusing at 102° , can be heated to 360° without decomposition; boiling at that temperature; hardly soluble in cold, but more readily so in hot water; very readily soluble in alcohol and ether. Acridine, $\text{C}_{13}\text{H}_9\text{N}$, is a strong basic body, uniting with acids to form salts which, like the base itself, are very biting and acrid substances.

On Pyren.—C. Graebe.—The substance just named has been found, by the author, among products containing anthracene. Pyren is a solid, crystalline substance, fusing at 142° , readily soluble in boiling alcohol, in benzol, ether, and sulphide of carbon. This body combines with picric acid, forming a peculiarly characteristic red-coloured crystalline compound, C_{14}H_8 + $\text{C}_6\text{H}_2(\text{NO}_2)_3\text{O}_6$. Pyren is also characterised by forming, very readily, various substitution compounds, several of which are described in this paper.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, August, 1870.

The July number of this periodical not having yet arrived, will be quoted afterwards. This number contains the following original papers:—

Stassfurt and its Industry.—J. Wolff.—The town of Stassfurt is situated in Prussia, Regierungsbezirk (County) of Magdeburg. This lengthy paper gives a detailed account of the enormously extensive beds of salt wrought near and under the town alluded to since the year 1823. The material, known as *Abraum salze* (there is no proper equivalent English word for this substantive, the nearest approach being *residual salts*), contains a mixture of carnallite (chiefly a compound of the joint chlorides of potassium and magnesium with water, and is worked for potassa, since it may contain up to 26.8 per cent of chloride of potassium), kieserite, polyhalite, and, more rarely, tachhydrite, kainite, and sylvine. A new mineral, called Stassfurtite, or boracite, has also been met with; its composition is expressed by $20\text{MgO} \cdot 4\text{BO}_3 + \text{MgCl} + \text{H}_2\text{O}$. Among the products of this district, bromine is one of the chief chemical substances, now manufactured by Dr. Frank to a quantity of from 120 to 150 lbs. per day. The bromine is obtained from the residual mother liquors.

Production of Opium from the Papaver Plants Cultivated in Germany.—E. Schwend.—This paper contains the author's account of a series of practical experiments instituted on a sufficiently large scale. The result is, that 1 hectare of land yields 10 lbs. of opium, and, moreover, 15 cwts. of poppy seed, from which a fatty oil is obtainable. Nothing is stated in reference to the value of this opium—viz., the quantity of morphia contained in it.

Contribution to the History of some of the Alkaloids.—Dr. Th. Husemann.—This first portion of a lengthy monograph treats on the aemine alkaloids, but the subject is chiefly considered pharmacodynamically and toxicologically.

Revue Hebdomadaire de Chimie, September 8, 1870.

Whilst this number has come to hand, several others, published before this date, have not arrived; and most of the other French periodicals are wanting. This may be readily accounted for by the events of the day.

Treatment of Wood in order to make it a Suitable Material for Paper Manufacture.—M. Méné.—The wood, previously reduced to the state of hives or sawdust, is placed for a time (the duration of which depends upon the nature and state of division of the wood) into water, being left there to rest, as is done with flax. By this treatment, a great many substances are removed from the wood, which is thereby afterwards more readily pulped. The rotting in water has the effect of disintegrating and partly decomposing the nitrogenous and interesting matter of the wood, which is also afterwards more readily bleached, rather coming yellow by the use of chlorine, as is the case where these matters have been left in the wood. The rotted wood is, previously to any other treatment, thoroughly washed with boiling water and steamed, and next treated with an alkali.

NOTES AND QUERIES.

Carbonic Ether.—I wish to purchase a small quantity of carbonic ether. I have tried most of the houses in London, but without success, and should feel obliged if you could direct me where it is to be obtained.—H. S.

Manufacture of Sulphuric Acid.—Can any of your readers inform the writer what is meant by a new process for economising nitrate of soda in the manufacture of sulphuric acid, called the "oxygenised," or "oxygenising" process?—A MANUFACTURER.

Bleaching Wax.—Will you kindly inform me—(1) The easiest method of bleaching paraffin-wax and bees'-wax, and rendering it transparent. (2) What chemical is used in the transaction, and, likewise, the quantity required to bleach, &c., 1 cwt., and the cost of the same? I have a friend, and he says he can do it in one hour, and render it white and transparent.—F. C. TERRELL.

Hofmann's Violet.—"Querist" wishes to be informed whether the process for the manufacture of Hofmann's violet by aid of the iodides of the alcohol radicals is still worked, and how the iodine is recovered? "Querist" reads, in the "Couleurs d'Aniline" of the "Encyclopédie Roret" that M. Levinstein patented a process, in which he uses nitrate of ethyl instead of iodide. Is this process worked? if not, why?

Starch and Alcohol.—(Reply to "Sciologist.")—As regards the correct composition and atomic weight of starch, it would be almost impossible to quote here more than this: that the formula of the perfectly dry substance is usually taken as $\text{C}_{12}\text{H}_{20}\text{O}_{10}$; and, for all practical purposes, this may answer. The quantity of alcohol obtainable from 100 parts of starch is about 567.8 parts, varying slightly in consequence of the fact that, during the different operations by which alcohol (the ultimate product of the vinous fermentation) is formed, there are generated, in larger or smaller quantities, certain by-products, among which are glycerine and succinic acid. The mode of conducting the operations, as well as the raw material employed, influence, more or less, the quantity of alcohol which 100 parts of starch yield. In practice, on the large scale, the true theoretical quantity cannot be obtained, because it implies perfectly pure materials and a perfect mode of operating, whereby no loss should occur.

Extract of Indigo.—(Reply to "Indigo.")—We do not understand what you mean by "weighting"; but perhaps it may be of use to you to say that a small quantity of glycerine is sometimes added to the substance you allude to. Since the quantity of indigotine present in indigo varies very considerably, it is clear that we cannot tell you what the greatest amount of extract is which can be obtained from 1 lb. of indigo; while, moreover, the quantity obtainable depends upon the proper manipulation in preparing the extract. The best, but also the most troublesome and expensive, method of getting rid of the greenish hue you allude to, is to prepare what is known as refined indigo. Since space forbids us to enter here into further details on this subject, and since you wish for a book which will give you some information, we refer you, for the present, to "Lectures on Coal-Tar Colours and on Recent Improvements and Progress in Dyeing and Calico-Printing," by Dr. F. Grace Calvert (published at Manchester by Palmer and Howe, and at London by Triibner and Co.) There is a large work in the press, by the Editor of this paper, which will contain full and ample details on this subject, so as to enable you to work on the large scale.

TO CORRESPONDENTS.

Z. Y. X.—Replies to querists must be sent in such a form that we can publish them. As we have often stated before, we decline to act as the medium for any secret communications. The proper course is for you to advertise.

Lee and Nightingale.—Mr. Alexander Gordon's paper, on "Lead Poisoning and its Prevention," has not yet been received.

Jonathan Bowen.—Articles, or lectures, on the subject of gases, by Dr. Odling, have frequently appeared in our columns. The notes you speak of have not been published.

Jas. Farie, W. H. Walcott, Dr. Phipson, and P. Holland.—Received.

VOL. XXII. No. 569.

ON THE TIME NEEDED FOR THE COMPLETION OF CHEMICAL CHANGE.*

By FERDINAND HURTER, Ph.D.

It is now nearly seventy years since Berthollet published his Essay on Chemical Statics, a work in which he tried to develop the principles of a then new science—the science of chemical statics.

We have not come very much nearer that final result of all chemical investigation, which Berthollet believed to be the science of chemical statics and mechanics, which would enable us to predict the phenomena from the preceding conditions.

The study of the rational composition of the chemical compounds has absorbed the attention of our eminent chemists so much that the dynamical part of our science has been but little regarded, and even the science of chemical statics is in but an imperfect condition.

Although our literature has augmented to an enormous extent, and although the science of chemistry is, in fact, the history of the force affinity, yet we cannot find means to measure the magnitude of that force. We speak of ferrous oxide, as possessing a greater affinity for oxygen than manganous oxide, but how much greater that affinity is, as yet unknown.

The magnitude of other forces is measured by the work done in a unit of time, or by the resistance necessary to prevent the force from doing the work.

Now we know that 98 parts of hydric sulphate dissolve 65.4 parts of metallic zinc; this affords, however, no measure for the affinity of hydric sulphate to zinc. A physicist would not be content to know that a certain force may remove or lift a certain weight, but he would inquire, "What time does the force need in order to complete this work?" In the eyes of a physicist, the measure of the force which caused the solution of zinc in hydric sulphate would only be complete if we knew, besides the acting quantities, also the time which the reaction occupies.

These are the reasons which induced me to ascertain the time needed for the completion of chemical reactions.

I will now try to develop a formula which shall express the relation existing between the work done and the time required to do it. Let us take any reaction which occupies considerable time to complete itself—for example, the dissolving action of hydric sulphate on metallic zinc.

Let us, for simplicity's sake, assume a piece of zinc of prismatic form, having a base of 1 centimetre square, to be exposed to the action of sulphuric acid. Let us also suppose the piece of zinc to be protected on all its sides, except its base, against the action of the acid.

In the first particle of time, call it a second, a certain quantity of zinc will be dissolved, and an equivalent quantity of acid neutralised. Assuming that at the beginning of the reaction a quantity W_0 of sulphuric acid was present, we shall at the end of the first second only have a quantity W_1 available for action. In the second particle of time this process will repeat itself, and if we denominate the quantities of sulphuric acid left at the end of the first, second, third, &c., particle of time, with W_1, W_2, W_3 , we shall have a decreasing series of numbers, $W_0, W_1, W_2, W_3, \dots, W_n$, representing the decrease of acid in course of time.

The quantities of zinc dissolved in the acid in each second will, of course, be proportional to the quantities of

acid neutralised, as well as to the depths of the layers of zinc which disappeared in the consecutive seconds.

If we represent the depth of the various layers with $d_1, \dots, d_2, \dots, d_3$, &c., we shall have the proportion—

$$(1.) d_1 : d_2 : d_3 = W_0 - W_1 : W_1 - W_2 : W_2 - W_3.$$

It is, further, clear that the action on the zinc, and, consequently, the depth of the disappearing layer, will be proportional to the number of particles of hydric sulphate, which exercise their influence in each moment on the exposed surface. If the molecular forces do at all act through space, the number of particles of hydric sulphate in the sphere of attraction of the exposed surface must itself be proportional to the whole quantity of acid present. I assume that molecular forces do act through distance, although but a small one. I therefore say that the quantities of zinc dissolved, or the depth of the layers disappearing, are proportional to the quantities of acid present in each moment. Now at the beginning we have the quantity W_0 , but at the end of the first second only W_1 , of acid exercising their influence. It is clear that we may replace the gradually diminishing force by a constant one acting during the same time, and we may therefore say that—

$$(2.) d_1 : d_2 : d_3 = W_0 + W_1 : W_1 + W_2 : W_2 + W_3.$$

From proportion (1) and (2) we obtain—

$$(3.) \frac{W_0 + W_1}{W_1 + W_2} = \frac{W_0 - W_1}{W_1 - W_2}$$

If we reduce this equation we shall have—

$$W_1^2 = W_0 \cdot W_2.$$

Had we used the more general terms, viz.—

$$W_{n-1}, W_n, W_{(n+1)},$$

we would likewise have obtained—

$$W_n^2 = W_{(n-1)} \cdot W_{(n+1)}.$$

This equation indicates that the series of numbers, representing the decrease of acid in course of time, forms a geometrical progression. I may, consequently, use the laws of geometrical progressions for my further demonstrations.

According to these laws, any one member of a geometrical progression may be calculated if the first member and the second are known. We shall therefore be able to calculate the quantity of acid left at the end of any one second if W_0 and W_1 are given.

The rule by which W_n is found is expressed in the formula—

$$W_n = \left(\frac{W_1}{W_0}\right)^n \cdot W_0$$

or, if we put $\alpha = \frac{W_1}{W_0}$, we have $W_n = \alpha^n \cdot W_0$.

In order to calculate the time necessary for the solution of the whole of the zinc, we have but to choose W_n so that $W_0 - W_n$ is the equivalent quantity of acid to the piece of zinc in question. If we then take the logarithmic form of the last equation, we shall find—

$$n = \frac{\log. W_n - \log. W_0}{\log. \alpha}$$

where n represents the number of seconds necessary to dissolve the whole of the zinc.

Let us now assume that the zinc had another area, larger or smaller than in the previous case—say c centimetres square = A . Then this piece would evidently be equal in its action to c pieces of the former sort. The quantity of acid available for action would decrease more rapidly. Our formula tells us that one piece of zinc is able to reduce the quantity of acid in n seconds from W_0 to $\alpha^n W_0$. If we desire to know the quantity of acid left after n seconds, when c pieces of zinc are acting, we shall have to apply our co-efficient of diminution, α^n , c times, in order to find W_n . We shall therefore have $W_n = \alpha^{n \cdot c} W_0$; or, denoting with A the area of the piece of zinc, $W_n = \alpha^{nA} W_0$. From this equation we derive the following one:—

$$n = \frac{\log. W_n - \log. W_0}{A \log. \alpha}$$

* Abstract of a paper read before the British Association, Liverpool Meeting, Section B.

From this formula, a great many interesting conclusions may be drawn.

We leave the numerous examples which might be and were produced: we will only cite the most interesting one, in order to prove the truth of the mathematical deductions.

The oxidation of manganous oxide, as carried on on a large scale under the name of "Weldon's process," is a subject with which the British Association is well acquainted. The manganous oxide is suspended as a fine precipitate in an alkaline solution of calcium oxychloride, through which a certain number of air bubbles rise in a given time. The manganous oxide offers an infinite surface to the limited surface of the air bubbles. The manganous oxide represents the sulphuric acid, and the air bubbles the zinc, of the former examples. If we, therefore, apply our formulæ to this example, we shall be able to calculate the quantity of manganous oxide left unoxidised after any period of time, assuming α^A to be given. Now, if the blast-engines supply, in equal periods, equal quantities of air, we may assume α^A to be constant throughout the process. This is, however, not always the case, and it is somewhat difficult, on this account, to find examples which agree perfectly with the formula. The manganous oxide itself seems to exercise different affinities towards oxygen under different conditions of alkalinity. It is, therefore, not to be expected that the results should always agree with the theoretical requirements.

In the works of Messrs. Gaskell, Deacon, and Co. in one case, a quantity of manganous oxide was converted into peroxide amounting to 19 per cent at the end of the first half hour. At the end of the fourth hour it proved, on analysis, that 81 per cent had been converted into binoxide. The question arises, what time would, theoretically, have been necessary to complete the oxidation as far as 81 per cent, if we know that in half an hour 19 per cent have been converted. By applying our formula for the determination of time to this case we arrive at the answer, 3.94 hours.

In another case the amount of peroxide of manganese formed was 58.5 per cent after two hours oxidation; at the end of four hours it amounted to 82 per cent. Our formula requires for that purpose 3.90 hours.

In a third case the amount of converted manganous oxide amounted to 67.4 per cent after three hours oxidation. To the question, how much would have been converted after five hours, our formula would give the answer 84.5 per cent; in reality it amounted to 84.4 per cent.

Gaskell, Deacon, and Co. used for some time only one blast engine. When they tried to use two, it was found that the two engines would do the same work in half the time. These facts clearly prove that the mathematical deductions are a general truth.

It may finally be mentioned, that for experimental researches, intending to obtain real values for the coefficient α , the formulæ require considerable extension. We have to take notice of the concentration and temperature of the reagents. We cannot experiment on a piece of zinc in the way I indicated, and we have to introduce the surface as a function of time, as it constantly varies. I believe, however, that the co-efficient α will prove a measure for affinity, because it expresses the work done by affinity in the unit of time.

The marvellous relation which Professor Bunsen found to exist between volatility of substances and their molecular weights, and which he found by measuring the time needed for the volatilisation of various compounds, gives me hope that I shall meet in the results of my further studies on this subject that simplicity which generally characterises the laws of nature.*

* When writing this paper I was not perfectly acquainted with the admirable researches of Professor Vernon Harcourt on the same subject. I am glad to find that my results, as far as they go, agree with those previously found by that gentleman.

ALLOYS OF COPPER, TIN, ZINC, AND LEAD, WITH MANGANESE.*

By J. FENWICK ALLEN, F.C.S.

IN the year 1826 a spoon, made by Messrs. Zernecke, of Berlin, was analysed, and the alloy was found to be composed of—

Copper	57.1 per cent.
Manganese ..	19.7 "
Zinc	23.2 "

This analysis is included in a chapter on Kupfermangan, by Mr. Johann Zenner, in his "Handbuch der Metall Legimngen," published at Quedlinburg.

Berthier produced a large number of alloys of manganese with various metals, and has recorded their principal properties.

Although there is no published account of such experiments, Dr. Percy has informed me, that some years ago he thoroughly investigated the nature of manganese alloys.

There are also specifications of patents, one in the name of Emil Stoehr, dated 1862, the other in the name of Oscar Priegur, dated 1864; both claiming the original discovery of this class of alloy.

Whilst, therefore, the alloys of copper, zinc, and other metals with manganese have been more or less known to the metallurgist for more than forty years; whilst their valuable physical properties have been fully described; whilst, moreover, manganese in its ores almost approaches iron in its abundance and in its cheapness; and, whilst for years being suffered to escape as a waste product from almost every large alkali works, we find the metallurgist has not succeeded in reducing it to serve as widely except when yoked with iron. We now claim for it a nobler affinity and a higher service.

Having had my attention directed to the subject by the late Mr. John Keates, whose name and memory, by those in this locality who leaned to science still are cherished, I have made it my study, and have been enabled to apprehend the causes that have prevented the general application of this most useful class of alloys.

To produce metallic manganese was not from the first attempted; it is with extreme difficulty that even the smallest quantities of this metal can be produced; these few pills were obtained only after the oxide mixed with charcoal had been subjected, in a plumbago crucible, to an intense heat for two or three hours.

From the first also I discarded using any of the ores of manganese, the iron and the silicon completely destroying the value of the product. Having obtained a comparatively pure oxide of manganese, recovered from the still-liquor, and having mixed this with oxide of copper, not metallic copper, together with wood charcoal, all finely ground and intimately mixed, the charge was put into a plumbago crucible, then heated in an air furnace at an intense heat for from three to four hours. It was found when the pot was taken out, that, still suspended in the charcoal, and not run down to the bottom, were innumerable fine shots of a bright white metal; these being separated by washing and placed again in the crucible and heated, fused, I may say easily, into a prill or button covered with a green layer of vitreous slag.

The process was continued until some ingots were produced, and in these experiments were made as to their malleability and ductility. This knife-blade is the first piece that was successfully passed through the rolls.

The alloy was found to be very hard and very brittle when hot, but when cold, although still hard, it rolled with ease and was highly elastic.

The proportions of the alloy were about—

Copper	75 per cent.
Manganese ..	25 "

* Read before the British Association, Liverpool Meeting, Section B.

When the simple alloy had been produced in sufficient quantities, compound alloys with zinc were tried in various proportions, and these again rolled with complete success.

Certain mixtures of copper, zinc, and manganese possess the advantage both over German silver and yellow metal, that, whereas, the one will only roll cold, and the other hot, the manganese alloy rolls from hot to cold.

The laboratory experiments having been completed, an air furnace was built in which a 100 lb. plumbago crucible was used.

The results were precisely the same as those obtained in the laboratory, only it was found that, by stirring the charge a few minutes before the crucible was taken out of the fire, by far the greater portion of the metal that before was in small fine shot, needing very careful washing, now settled to the bottom of the pot, and could be poured out as a bar or ingot, the slag also melting, and the unconsumed charcoal floating on the top. This experiment was continued until several hundredweights of the alloy were produced, so that it may be subjected to various tests, and also that some approximate estimate of its cost and value might be formed.

As a simple alloy, in which the proportions of manganese ranged from 5 per cent to 30 per cent, it is both malleable and ductile, with a tenacity considerably greater than that of copper.

With zinc a compound alloy very closely resembling some of the qualities, not the best, of German silver is obtained. The alloy of copper and manganese would also combine with tin, lead, and other metals, and from these castings were made which were applied as bearings for machinery.

It was not the nature of the metal in itself that prevented its being widely used; it was its cost. The waste of manganese is very considerable, over 10 per cent remaining unreduced and forming a silicate; the wear and tear of the plumbago pots and the furnace itself incurred a large expense; and in proportion to the quantity of metal produced, the fuel consumed, and the labour expended, were great. The work was, therefore, for a time arrested by an obstacle which not unfrequently bars the path of the inventor. It was, however, now a question of cost, and a firm belief that a material so abundant, and a product so valuable, had a destiny, enabled one to look hopefully on the dilapidated furnace and the unused metal. The waste of manganese in alloys rich in that metal will, we fear, always be considerable; but the value of the raw material would permit some such loss, could the other points be attained; and these, we believe, have to be achieved. These ingots have been produced by heating the mixture of carbonate of manganese with oxide of copper and charcoal in a tolerably large reverberatory furnace, and not in a small and costly pot. The fuel used has been principally the common slack, or small coal of the district, and not coke; the labour has been proportionately reduced; and we believe you have before you a series of alloys that will ere long play no unimportant part in the manufactures of our country.

It behoves one to say that it is the beautiful furnace arrangement of Mr. Siemens that has enabled us to overcome our difficulties. A furnace planned by Mr. Siemens has supplied the intense heat needed, with a non-oxidising flame, in a quiet atmosphere.

It merely remains for me now to place before you the following series of specimens.

- 1st. Manganese and copper in various proportions from 35 per cent to 5 per cent of iron, as ingot, sheet, or wire.
- 2nd. Copper, zinc, and manganese, also in different proportions, and in a variety of applications.
- 3rd. Copper, zinc, manganese, and tin as ingots and as bearing.
- 4th. Copper, manganese, and tin in several different proportions as bars.
- 5th. Copper, manganese, and lead.

ON ARTIFICIAL STONE AND VARIOUS KINDS OF SILICA.*

By the Rev. H. HIGHTON, M.A.

SILICA is found in various forms more or less soluble. Some kinds can only be united with alkalies in the heat of a glass furnace; other kinds can be dissolved under a high pressure and after a considerable lapse of time by solutions of alkalies; other forms, again, to which the author particularly wished to call attention, can be dissolved under proper precautions even in the cold. Natural silica of this kind was exhibited both from Germany and England. By means of this soluble silica artificial stone can be formed harder than any natural stone except the very hard granites and primitive rocks. The process is as follows:—

A concrete is made with any good hydraulic cement. When this is dry it is steeped in an alkaline solution of silica, in which is placed a quantity of free silica. The following chemical process then takes place:—The lime in the concrete extracts the silica from the solution, leaving the alkali free, which immediately attacks the free silica and conveys it in its turn to the concrete. This process goes on continually till the lime in the concrete is saturated with silica. By this process, within a week the strength of the concrete is increased from 50 to 150 per cent, and by a longer continuation of the steeping the strength is still more increased.

As the alkali acts only as a carrier of the silica, it is used over and over again; and it is in this that the economy of the manufacture consists.

The following is the comparative resistance to a crushing force of several kinds of stone:—

	Per sq. inch. lbs.
The Silicated Concrete, or Patent	
Victoria Stone	6441
Aberdeen Granite	7770
Dartmoor Granite	6993
Peterhead Granite	6216
Yorkshire Landing	5851
Stafford Blue Brick	4032
Portland Stone	2426
Bath Stone	1244

The stone formed in this manner has been tried as a pavement in the busiest part of Cheapside, and in many other parts of London, and for steps, lintels, sills, &c., in many parts both of this kingdom and abroad as well as in India.

The whole of the stone in the new warehouses, 27, St. Mary Axe, is made in this manner.

As a cheap strong stone, when manufactured on a large scale, it is likely to supersede natural stone, except where the latter is very cheap and abundant.

In localities, as on the Thames, where there are facilities for obtaining good hydraulic cement and hard broken stone, it can be manufactured at a much lower cost than Yorkshire or other stone can be procured.

ON THE ANTISEPTIC TREATMENT OF CONTAGION AS ILLUSTRATIVE OF THE GERM THEORY OF DISEASE.†

By WILLIAM HOPE, V.C.

At an experimental farm belonging to a company in which I was interested pecuniarily and scientifically, rinderpest broke out in the summer of 1867 among a herd of 260 or 270 cows. I sent for Professor Brown from the

* Abstract of a paper read before the British Association, Liverpool Meeting, Section B.

† Read before the British Association, Liverpool Meeting.

Privy Council, who, after making his inspection, said he had found every symptom of rinderpest except one, and that was one of the later symptoms generally, although not invariably, preceding death, namely ulceration of the mouth. Next the dreaded ulcers appeared, and Professor Brown told me there was no means of cure known to science, that the disease was practically incurable, that in the present instance there was no sober, serious chance of saving a single animal out of the whole herd. At my particular request Professor Brown explained the progress of the disease, and the peculiar difficulties to be encountered.

Immediately afterwards I undertook the treatment of one-half of the animals. I got all the quick-lime I could lay my hands on, with which I formed broad roadways all round the sheds, three or four inches in depth, and placed pyramids of it along the pathways in the sheds, and slaked it *in situ*, until all the animals were coughing and choking to an alarming extent. I then obtained the report of the Royal Commission on the Cattle Plague, and specially studied the experiments made by Mr. Crookes, F.R.S., which chimed in exactly with my own instincts, and his reasoning being logical and scientific he made a disciple of me at once. I therefore telegraphed to Manchester for a barrel of genuine carbolic acid, and determined upon combining the two treatments of liquid diet for the purpose of guarding against the secondary symptoms, with what I might term the chemical treatment recommended by Mr. Crookes. The result was that, while every single animal that I did not take charge of either died or was slaughtered, I succeeded in saving every single animal that I did take charge of; and if you consider the very large scale on which my operations were conducted, the completeness and thoroughness with which the infection had been disseminated throughout the herd, and the fact that rinderpest is the most infectious of all disorders, whether among mankind or the animal creation, known to science, no one can, I think, doubt that the treatment suggested by Mr. Crookes is a radical and complete specific against rinderpest.

What I wish to call the attention of the section to is the fact that I saved the lives of those animals not by any medical treatment, properly so-called, of the animals themselves, but by an unremitting, ceaseless chemical onslaught on the germs of the disease. I argued in my own mind that a theory such as the germ theory of disease could not, in the nature of things, be partially true; it must either be altogether true or altogether false. If true, it was the most hopeful theory that anyone could comfort himself with in face of an outbreak of zymotic disease, because it afforded some firm and sure foundation for treatment. A purely medical treatment, properly so-called, of infectious disease, always has appeared to me, if I may be pardoned for the expression of so heretical an opinion in such orthodox company, to be empirical to the last degree.

It is probable that medicines act physically as well as chemically, but I am not aware that anyone has been able to give a very satisfactory explanation either of the physical or the chemical action of organic medicines, whether exhibited in the human subject or in a lower organism. The chemical action of many inorganic medicines is, no doubt, perfectly understood; but even the administration in the nursery of a home-prescribed dose of rhubarb and magnesia has always seemed to me the height of empiricism, for here the nurse boldly invites the actions of inorganic and of organic substances, although, no doubt, she exhibits her agents with, on the whole, a happy result. But at last we appear to be getting upon some firm scientific footing, for clearly it is more scientific to attack the germs producing disease with a chemical agent whose action is ascertained, than to exhibit in the inside of the patient affected a variety of organic and inorganic substances which can only at best act upon the disease, that is upon the germ, through the secondary agency of the patient himself. Of course in rinderpest,

or in any other infectious disease, the disorder may have proceeded too far before the patient is taken in hand to admit of the possibility of a cure, and death may result from a secondary action set up during the progress of the disease, even although the primary cause of the disease—that is, the germs—may have been altogether exterminated. But it has always seemed to me that this case of the chemical treatment of rinderpest upon so large a scale, is one of the most entirely practical proofs of the germ theory of disease that has yet been obtained, and it is for this reason that I have ventured to communicate these details to this section. In doing so I am anxious to explain distinctly what it is that I mean by the words “germ theory of disease,” for the words are so often used that many persons attach various meanings to them.

By the “germ theory of disease” I simply mean the process by which an infectious disease having once originated is disseminated and communicated from one subject to another. I do not desire to apply it in any way to the origin of such diseases. Probably we shall never know the truth as to their origin, for it is difficult to see how any accurate observations can be conducted upon such a point. I therefore wish Mr. Crookes's chemical treatment for infection, as successfully carried out in the case above described, to be considered as evidence only in favour of the theory that infectious disease is propagated not originated, on what is known as the germ theory. Of the origin of such diseases I will merely say this—that I have the greatest possible difficulty in believing that the germs of Asiatic cholera existed in a passive state from the creation of the world, whenever that may have been—on which point again I would offer no opinion, for I fear that I am getting on dangerous ground—down to the year 1817, when suddenly called into existence by getting into the congenial climate of a Hindoo stomach.

Perhaps I should now communicate a further experiment that circumstances forced upon me in the chemical treatment as disease attacking, as distinguished from medical treatment of the patient attacked, in this next instance, as I am almost afraid to confess, in the human subject. Turning again to the paper from which I read an extract, I will read a prophecy which I was rash enough to publish at the end of it, in, as you will recollect, the month of November, 1867, that similar treatment would, for similar reasons, prove equally successful in diseases attacking human beings. After reading the passage in question, Mr. Hope proceeded to say:—In the spring of the following year, namely, 1868, I returned home late one Saturday evening, and found, to my horror, that my eldest child was laid up with a violent attack of scarlet fever. It so happened that scarlet fever was the disease, of all others, that I most dreaded for children; and this was a violent attack, with acute symptoms both in the throat and of fever. My wife, however, having authorised the exhibition of carbolic acid, and having already isolated the child, I proceeded chemically to attack his enemy, the scarlet fever germs. The first step was to kill the germs which caused the pain in the throat and the difficulty in swallowing. This was effected by a gargle of one part of carbolic acid—I mean of the pure white carbolic acid manufactured by Calvert—to 200 parts of water. The effect was instantaneous, and the result most encouraging. Our efforts were redoubled. We attacked the germs in every direction, and showed them no mercy. Cloths dipped in a 2 per cent solution of carbolic acid were hung up over the bed and in different parts of the room. The same 2 per cent solution was sprinkled over the bed clothes and over the carpet and furniture. A basin of the same was always kept at the door of the dressing-room, through which alone ingress and egress were permitted, so that the few persons allowed to come into the room might wash their hands in it before going to other parts of the house. During all Sunday and all Sunday night the same treatment was incessantly kept up, and the patient took occasionally small sips of a solution

as weak as 0.2 to 0.3 per cent, and the poor germs of the scarlet fever could not get any rest, and could find no place of security. The result was that when the Monday morning came, the patient was fast approaching convalescence. I should mention that some very simple febrifuges had been given to the patient in addition to the carbolic acid which had been administered to the disease. I have not preserved a record of how these were given, but I am quite sure that if I had there is no one in this room who would say that they were sufficient by themselves to cure a bad case of scarlet fever. Convalescence proceeded most satisfactorily. When the peeling stage arrived, the entire skin of the child was washed all over from time to time with a 1 per cent solution of carbolic acid, and he eventually made a perfect recovery without a relapse, and without any of those dreaded after-consequences which are so disastrous in many cases. Before, however, he could have been certified as safe for other children to approach, some members of the household displayed a somewhat rebellious spirit towards the restrictions imposed on communication with the invalid; and on my return from London one evening I was shocked to learn from my wife, who understood the danger, that several such visits had been paid to the patient when she was off sentry. Up to that time—the patient having been at once isolated, and rigorous measures of disinfection carried out all through the house, as well as in the sick room—the infection had not spread. But I said at once that all our previous care was now thrown away; and it proved to be the case, as in a few days the other children were all attacked also. But the enemy being in their case fiercely assaulted by carbolic acid on his very first appearance, their cases were much milder than the first attack. In the case of a child of about one year old, the carbolic acid was applied to his throat by the steam of hot water, which he was made to inhale, in every instance with the happiest effect. Eventually the disease was entirely burnt out; the recoveries were in each case most satisfactory, and in no case were there any bad after results. This instance by itself would not, of course, carry very much weight, but following a case on so great a scale as that I previously described, and the treatment being the direct consequence of the former, and based upon a distinct and intelligible theory, I have thought that you would consider it also of some interest.

DUST AS A FERMENT.

By CHARLES R. C. TICHBORNE, F.C.S., M.R.I.A.,
Chemist to the Apothecaries' Hall of Ireland, &c.

THE celebrated lecture and papers upon "Atmospheric Dust," published last year by Professor Tyndall, brought prominently before the public a subject which is intimately connected with the one which I have taken for my text on this occasion, and which for many years I have looked upon as one of our most fertile sources of diseases in large towns, having, in 1866, when the cholera was raging in Dublin, drawn attention to the dangerous character of our street dust.*

It is, however, my intention, in the present paper, to place simply on record some experiments which have been performed from time to time and all bearing upon this most important subject.

Metropolitan towns are unfortunately those which, as a rule, suffer most from zymotic diseases, for the accumulations in a town of importance bring their attendant ills. Every acre of buildings, and every 1000 of increase in population, bring irremovable dirt. The vitiation of localities is not merely a matter of the numerical proportion of the inhabitants, but it becomes changed in character and more dangerous from the destruction of the numerous compensators or renovators provided by nature. The population seek suburban dwellings, and expend

fabulous sums in the extra expenses incurred thereby. Those who are forced to remain in the seething mass are, but too frequently, those who suffer most from this dirt, and who, from their careless habits of living tend most towards its advancement.

A good supply of water has been insisted upon for many years, and sanitary measures have been taken in most large towns in regard to this important subject. The gaseous condition of the atmosphere has also received some considerable attention, particularly in connection with the effects produced by manufactories. I cannot help thinking that, as regards epidemic diseases at least, the influence of these sources of contamination has been a little exaggerated, except in the cases of a few of the direct blood-poisoners, such as sulphuretted hydrogen. A most important substance, however, in connection with our sanitary condition, is what has been termed "Atmospheric Dust," or the floating solid constituents of our air. Although well known, it was not much investigated from a scientific point of view in this country until Dr. Tyndall, Professor Lister, and a few others drew attention to it. Tyndall in his experiments has demonstrated, however, one important point, namely, that this atmospheric dust may be viewed as organic matter. But its proximate analysis is one of extreme difficulty, and the researches which have been made in this direction do not throw much light upon the subject. Dr. Angus Smith has, however, with great perseverance, worked out some valuable facts, bearing upon this part of the investigation.

It is evident from the difficulty in giving a critical examination of atmospheric dust that the point of enquiry tends more in the direction of the local pabulum of these particles, and here it may be as well to state that I strictly confine the term atmospheric dust to that dust which floats at a certain altitude, and which has been winnowed from the inorganic particles, except small traces of sodium that are not worth consideration. It is this organic portion that contains the germs which, if not absolutely essential to all changes coming under the names of fermentation and putrefaction, are the prime movers in such phenomena. As Professor Lister says:—"The spores, besides being produced in incalculable multitudes, are of extreme minuteness, and constitute a very fine dust, which cannot fail to be wafted and extensively diffused through the air." "The particles of dust which are rendered visible to the eye by being illuminated are gross compared with the spores of a fungus."

As regards much of the pabulum of the atmospheric ferments and the ferment itself, it lies on our shelves, floors, and streets. This is the nest in which germinal matter is fostered and wafted through our atmosphere. Each dust must partake more or less of the local condition of the place.*

The following paper is written with a view to give the analysis of some of this dust, which, to a certain extent, may be considered as typical; also to determine as far as possible their chemical activity as ferments, or their adaptability to become ferments.

Street Dust.

The two following samples were taken from our principal streets, both of which are paved with a very hard and non-absorbent stone.

Grafton Street Dust, dried at 100° C.

Inorganic matter	68.9
Organic	31.1
(Containing nitrogen, 1.07; carbon, 43.7)	100.0

Nassau Street.

Inorganic matter	54.8
Organic	45.2
(Containing nitrogen, 2.1; carbon, 57.5)	100.0

* Dr. Percy says that the Library of the British Museum gives a dust having 50 per cent of organic matter in it. ("Dust and Disease," page 4.)

* Vide CHEMICAL NEWS, July 5th, 1867; Irish Times, Oct. 9, 1866.

The organic matter in both these dusts consists of stable manure finely ground; a glass of very low power was all that was necessary to prove this fact, but part of it, from its minute state of division, was evidently very old.

Nassau Street Dust was taken from the locality of a cab stand, and the organic matter was here in an incipient state of change; it exhibited traces of ammonia, whilst these street dusts as a rule generally give, if anything, a slightly acid reaction. Street dust, then, consists of stable manure and stone finely ground; the traffic on the streets supplying the grinding power. On a macadamised road, irrespective of the effects of the traffic, the inorganic matter greatly preponderates, and as it is soil with which the animal matter is attenuated, the mischief is at its minimum. Not so as regards the streets of large municipal boroughs, which are generally paved with a hard stone, which would have no other effect upon this substance than that of an attenuator.

Dust taken from the Top Seats at Merrion Hall, Dublin.

Organic matter	32.1
Inorganic matter	67.9
	100.0

Dust from Gallery of the Theatre Royal, Dublin.

Organic matter	53.2
Inorganic matter	46.8
	100.0

Dust from the Ventilatory Space above the Gas in Ancient Concert Room, Dublin.

Organic matter	35.7
Inorganic matter	64.3
	100.0

These three last specimens as regards general appearance resemble each other considerably. Merrion Hall is the largest place of worship in Dublin, and is comparatively a new building. The other two buildings are much older. The Theatre we presume receives a much greater number of visitors in the course of the tenanted months. All these buildings are well ventilated. The large amount of iron in the dust is peculiar; for instance, that obtained from the Ancient Concert Rooms gave 21 per cent as the amount of peroxide in the inorganic matter.

Dust from the Walls at the Top of Nelson's Pillar, Sackville Street, Dublin.

Organic matter	29.7
Inorganic matter	70.3
	100.0

Height, 134 feet.

This monument is built of granite, and the residue of inorganic matter in this case consisted of mica-felspar, &c. If we take into consideration the position and the difficulty in not detaching a considerable quantity of stone, although a feather was used, the amount of organic matter was truly extraordinary, and if we put it down as containing over 50 per cent of organic matter, as actually contained in the dust if it could have been removed by itself, we shall not be far off the mark.

Some further experiments were then instituted to determine how far, and to what extent, these dusts would operate as ferments, and a volumetric system of measuring the intensity of any process of fermentation was contrived. It enables the operator to watch the process much more definitely than he could by ordinary observation. The process is based upon the reduction of the nitrate of any base to a nitrite in the presence of substances undergoing fermentation. In these experiments the following precautionary measures were adopted, so that, as far as possible, all the fermentations induced were proper to the ferments used in the experiments.

Distilled water was taken and permanganate of potassium added until a distinct red colour remained, it was then distilled, the first portion being rejected. The remainder was then used for the experiments. The ashes of yeast may be employed to supply the mineral ingredients, but in these experiments a mixture of nitrate of potassium, phosphate of sodium, and a little sulphate of potassium and chalk to neutralise the acids formed were employed, the pabulum used being a mixture of cane and milk sugar. The mixtures were well boiled in each experiment in their respective flasks, and after closing with cotton wool and cooling, the ferments were added. They were all placed in a similar position and submitted to a pretty constant temperature night and day, varying from 20° to 28° C.

Expt. 1.—In this case the above mixture, which was found by experience to be one easily convertible into lactate of calcium in the presence of ferments, was submitted for some two to three weeks to the temperature conducive to such changes. It showed no decomposition for fourteen days, but at the expiration of that time there were indications of a fresh molecular arrangement, but no particular development of organisms. This evidently showed that the precautionary method taken for the destruction of the germinal matter had more or less been perfect. The opening and closing of the flask would more than account for the change evinced.

Expt. 2.—In this case $\frac{1}{4}$ of a grain of nitrate of potassium was used to the fluid ounce of the fermentable mixture. The ferment was the mould of cheese. It was examined from day to day in the following manner:—5 c.c. of the clear liquid were withdrawn with a graduated pipette, and the level of the remaining liquid marked on the flask, so that it can be made up to the original level if there is any loss from evaporation. The 5 c.c. were then mixed with a little mucilage of starch and iodide of potassium added. On acidulating with sulphuric acid, blue iodide of starch was at once formed, representing two N_2O_3 present. A volumetric solution of hyposulphite of sodium was then added until decolourisation of the iodide of starch took place. Each degree of hyposulphite consumed would represent 0.28 of a grain of nitrate as being reduced to nitrite.

	Nitrites.	Nitrates.	Remarks.
After the 1st 24 hours {	0.5 hyposulphite consumed.	Present.	Fermenting slowly.
" 2nd 24 hours {	Trace.	Present.	Increased fermentation.
" 3rd 24 hours {	None.	Present.	Vigorous fermentation, thick mycelium, and great quantity of spores

In seven days the liquid had become thick with the mycelium, and crusts of lactate of calcium began to form; in forty-eight hours afterwards the contents of the vessel were solid.

This experiment was repeated again, but with 3 grains of nitrate of potassium to the fluid ounce the results were different, for in this case nitrites were present during the whole of the fermentation. This is rather a curious observation, although the entire of the nitrates was not destroyed; the first instance we had little or no evidence of the nitrous acid. It is probable that in the reduction of the nitrates preparatory to the assimilation of its nitrogen, a nitrite is the first stage, but that if the ferment bears a considerable proportion to the nitrate present, or that the fermentation is going on very rapidly, the nitrogen will be assimilation in the form of some lower compound of nitrogen. There is no evidence of the molecule N_2O_3 during the fermentation, although the supernatant fluid is always slightly acid. One point of importance is evident that, in the examination of potable waters, if no nitrates are present, it is no proof that decomposition is not actually proceeding at the time as regards the organic matter therein.

Expt. 3.—Street dust was allowed to remain some time at a temperature of 20° to 28° C.; it became after a little

while covered with a thick mould. This mould acts as a ferment of great activity when placed in the saccharine mixture described above. After being partially dried it seemed more active, weight for weight, than the mould from rotten cheese.

The following results were obtained on fermenting the usual solutions of sugar, &c., with the addition of 3 grains of nitrate of potassium, and sufficient street dust to represent 1-2000th part of the entire mixture. (In adding this and the other dusts as ferments, only the organic portion was taken into consideration, the weighing being regulated accordingly.)

Days.	Degrees of volumetric solution of hyposulphite of sodium required to decolourise the iodide of starch from the liberated N_2O_5 in 5 c.c.	Remarks.
2	0.3	
3	3.5	{ Spores, &c., considerably developed. Fermentation very active; beautiful mass of mycelium.
4	9.5	
5	0.8	
6	8.5	{ Fermentation going on very actively. Fermentation very strong, large quantity of carbonic acid given off, and thick layers of mycelium on the surface.
7, 8, and 9	8.5, 7, and 2.5	
10 and 11	1	{ Fermentation on the decline. Liquid had become very thick and crusts of lactate of calcium beginning to form.

Expt. 4.—Was a similar examination of the activity of the dust obtained from Nelson's Pillar, a monument in Dublin, 1-2000th part being used.

Days.	Degrees of volumetric solution used	Remarks.
2	3.5	{ Thick coating of mycelium at once formed. Fermentation going on vigorously.
3 and 4	4 and 7	
6 and 7	8.5 and 8.5	{ Fermentation seemed upon the decline. Quite solid from lactate of calcium; vessels could be inverted without contents falling out.
10		

Expt. 5.—The dust from the Ancient Concert Rooms was obtained from the ventilating space above the public room. This, it will be remembered, contained a considerable percentage of iron.

Days.	Degrees of volumetric solution.	Remarks.
2	trace of nitrite	{ No perceptible sign of fermentation. Slight sign of fermentation.
3	1.0	
4	3.5	
5	9.0	{ Fermentation seemed on the decline.
7	10.0	
8 and 9	10.0	{ Fermentation seemed on the decline.
10	8.5	
12	4.0	{ Lactate of calcium began to form slowly.

Expts. 6 and 7 were, respectively, with dust from the Theatre Royal and Merrion Hall, Dublin. The first was almost exactly similar to the fifth experiment, but the dust from Merrion Hall approached more nearly to the fourth experiment in its results.

In conclusion, I may remark that, although if I had had time to repeat these experiments, many points in the

details of manipulation would have been improved, still the results are of some importance.

They conclusively prove the power of dust as an active ferment.* Also, the estimation of the N_2O_3 as a criterion of the extent, or intensity, of such an action is, I believe, capable of further development. Thus, a slight fermentation that would not probably be perceived could not escape observation by this method. These experiments, as far as they go, seem to point to a curious phase of the subject—that is, that dust taken at a great height, and in such a position as in the fourth experiment, should appear to have as great, or greater, activity than that which would be obtained from a building which is nightly crowded to suffocation. This, in some measure, may be due to the extreme levity of the spores, which are supposed to be the life of the dust, and which lightness may be described as almost approaching volatility. *There is, probably, an altitude of the maximum of activity for all localities as regards dust.* It is so light that even that obtained in an ordinary house contains a large portion that refuses to sink when thrown upon water; and, even when the vessel is placed beneath an air-pump, a large percentage floats. To me the activity of the dust taken from the top of the monument 134 feet high is something marvellous—this source so far removed from the busy streets—yet its organic matter contains what is capable of splitting up, in a short time, hundreds of times its own weight.

I am aware that the results obtained, and detailed in this paper, are not so elaborate as I should wish, but they are experiments in which time is an important item; they are, however, quite sufficient to prove the value of such investigations. Microscopy, at present, is not likely to throw much light upon this subject, except in conjunction with some such work as detailed in the present paper.

SOLAR SPECTROMETRY.

REVERSAL OF THE SODIUM LINES IN THE SPECTRUM OF THE UMBRA OF A LARGE SPOT NEAR THE EASTERN LIMB OF THE SUN.

JUST as we go to press we receive from Prof. Morton a letter with the following important communications by Prof. C. A. Young, which will appear in the next number of the *Journal of the Franklin Institute*. We have not time to get the drawings engraved, but Prof. Young is writing an article of some length, with numerous illustrations, which, through the kindness of Prof. Morton, we hope shortly to give.

Dartmouth College, Hanover, N.H., Sept. 26, 1870.

My dear Sir,—I write to inform you that, last Thursday, September 22nd, about 11 a.m. Hanover mean time, I was so fortunate as to see the sodium lines D_1 and D_2 reversed in the spectrum of the umbra of a large spot near the eastern limb of the sun. At the same time c and f lines were also reversed, but with the great dispersive power of my new spectroscopic I see this so often in the solar spots, that it has ceased to be remarkable. In the umbra of the spot the D_3 line was not visible, but in the penumbra was plainly seen, as a dark shade. I am not aware that this reversal of the sodium lines in a spot spectrum has ever been observed before; its reversal in the spectra of prominences is not very unusual. A small prominence on the western limb of the sun, which was visible the same forenoon, presented all the following bright lines, viz.: C, D_1 , D_2 , D_3 , $1474'$, b_1 , b_2 , b_3 , $1989'5$, $2001'5$, $2031'$, F, $2581'5$, $2796'$, and h; fifteen in all. In the

* If it is required to manufacture butyrate or lactate of calcium practically, I would never advise the use of cheese as a ferment, if any active dust could be got (I do not think there will be any difficulty as regards this point); to get rid of the quantity of extraneous matter which is introduced by the cheese is, however, very frequently very difficult. A little dust, separated from the coarser particles by elutriation, is the correct ferment.

spot spectrum the magnesium lines b_1 , b_2 , and b_3 were not reversed, but while the shade which accompanies the lines was perceptibly widened, the central black line itself was thinned and lightened.—Yours, &c.,

C. A. YOUNG.

Prof. Henry Morton.

PHOTOGRAPHS OF PROTUBERANCES ON THE SUN'S LIMB.

Dartmouth College, Hanover, N.H., Sept. 28, 1870.

My dear Sir,—I write to tell you that this afternoon, with the help of Mr. H. O. Bly, our photographer, who has assisted me in the matter with great skill and interest, I have succeeded in obtaining photographs of protuberances on the sun's limb, of which I enclose a specimen. They were obtained by attaching a small camera to the eyepiece of the telescope and opening the slit somewhat widely. We worked through the hydrogen line near α . As a picture, the little thing amounts to nothing, because the unsteadiness of the air and the mal-adjustment of the polar axis of the equatorial caused the image to shift its place slightly during the long exposure of three and a half minutes which was required, thus destroying all the details. Still, the double-headed form of the prominence is evident, and the possibility of taking photographs of these objects is established. Success will depend upon the use of more sensitive chemicals (those used to-day were such as are ordinarily employed for portraits), and a very careful adjustment of the equatorial axes and the clock-work. I fear a telescope of much larger aperture than mine will also be found necessary, in order to produce pictures that will really give much of an idea of the form and texture of these beautiful clouds. I may add, that between 3:50 and 4:30 o'clock this afternoon the umbra of the spot upon which I made the observation of the sodium lines, as communicated to you a few days ago, reversed the following lines (ranged in order of brightness), viz.: C , F , D_3 , 2796 K, (Hyd. γ), b_3 , b_1 , b_2 ; D_1 , D_2 , h , b_4 , and 1474 K. The brightness of b_3 was remarkable. Another spot, just south of this nucleus (which was the most southern of four in the same penumbra), also reversed the hydrogen lines very finely, and on opening the slit a little, it was found that the phenomena was caused by two enormous protuberances or luminous clouds, which in the spectroscope shone brightly even upon the surface of the sun. Their form could be distinctly traced—at 4:05 it was as given below: the right-hand one terminated in or close to the nucleus of the spot; the other and larger, in the penumbral region. The whole length in right ascension, determined by the time required for them to pass the slit when the clock work was stopped, was 16.5 secs. of time—a little more than 4' of arc, or 111,000 miles. They extended from the spot which was nearing the western limb, nearly to the centre of the sun. At five o'clock they were still visible, but much fainter. When brightest I was able to see their form, even through h ; the lines other than hydrogen which they showed (notably D_3), were limited to the immediate neighbourhood of the spot group.—Yours truly,

C. A. YOUNG.

Prof. Henry Morton.

NOTICES OF BOOKS.

Annual Report of the American Institute of the City of New York for the Years 1868 and 1869. Albany: The Argus Co., Printers.

WE owe to the kindness of the Directors of the American Institute the receipt of this large and valuable volume, a tangible proof of the interest taken by the citizens of the great Trans-Atlantic Republic, in science and its useful applications to the various pursuits of daily life. The volume before us, 1125 pp. in octavo, contains:—A review of the operations of the Institute, presented by the Board

of Trustees at the annual meeting, held on February 4th, 1869; an exhibit of the receipts and expenditures during the year; the annual reports of the several standing committees of the Institute; twelve scientific lectures delivered at Steinway Hall, in the city of New York, under the auspices of the American Institute; the transactions of the Farmers' Club, including communications from residents of other States; the proceedings of the Polytechnic Association, embracing notes on progress in science and art, both at home and abroad; and, lastly, the discussions of the Photographical Section of the American Institute. As a proof of the excellent arrangement of the Institute, we may state that, among others, it has committees for manufactures and machinery; chemistry, mineralogy, and geology; optical science; civil engineering and architecture; agriculture; horticulture; and commerce. Among the subjects of the lectures given we may notice the following:—"On the Philosophy of the Tea-Kettle," by Prof. Silliman; under this very homely title the eminent *savant* elucidates, in a very clear and precise manner, some of the most interesting facts bearing upon the doctrine of calorific and its application to steam machinery. "On the Telescope," by Prof. Alexander; the lecturer enters into some particulars now rarely, if at all, mentioned, bearing upon the invention of the telescope, which he clearly proves to be due to Hollanders. "On the Philosophy of the Oven," by Prof. Horsford; this lecture contains not only a valuable record of the principles involved in the art of making bread, but also interesting historical and archaeological matters. "On the Spectroscope," by Prof. J. T. Cooke; an excellent and very pleasantly written account of the spectroscope and its many applications. "On Modern Engineering," by the Hon. W. J. McAlpine; this paper, although brief, gives a complete review of the subject alluded to. These lectures, although occupying a comparatively small portion of this large volume, are among the most valuable of its contents, and are all and severally models of lectures, as they should be given, to unite the *utile dulci*. It is impossible to give even the briefest review of the varied contents of the rest of this volume, full as it is of useful and valuable information on so great a variety of subjects. As a work of reference this, the twenty-ninth, Annual Report of the American Institute of the City of New York, will form a valuable addition to European libraries and book-shelves.

CORRESPONDENCE.

PURE SCARLET.

To the Editor of the Chemical News.

SIR,—In this week's CHEMICAL NEWS (No. 568), appears a statement, copied from the *American Journal of Science*, relative to the fugacity of pure scarlet, of which a water-colour cake was purchased, made by the English firm of Messrs. Winsor and Newton. As the paragraph in question may tend to damage their reputation, permit me to observe that every artist knows or ought to know—for a knowledge of the materials of art is by no means universal—that pure scarlet is the most fugitive colour in the whole range of artistic pigments. In my edition* of "Field's Chromography, or Treatise on Colours and Pigments as used by Artists," this colour is noticed as follows:—

"Pure Scarlet, or Iodine Scarlet, is an iodide of mercury, having the body and opacity of vermillion, and being as much inferior to it in permanence as it is superior in brilliancy. Of all artistic pigments it is at once the most dazzling and the most fugitive, and should have no place on the palette. If used, it should be with an ivory knife, as iron and most metals change it to colours varying from yellow to black; hence it should never be com-

* London: Winsor and Newton, 1869.

pounded with metallic pigments. So sensitive, indeed, is it to the slightest touch of metal, that it has been known to turn to a dull brown merely by being washed over with a colour which had been taken out of its saucer with a penknife. In the cake, it must be carefully kept wrapped up in paper, otherwise the presence of metal tubes or a knife in the colour-box may spoil it. By a foul atmosphere the scarlet is utterly destroyed, and even metallised. In contact with the air it quickly fades away, and has been found to vanish completely when exposed to light alone. Employed in water, a thick glaze of gum-arabic or gamboge adds to its stability. As a landscape pigment, the colour is out of the general scale of nature, but in flower painting its charms are almost irresistible. Nothing, certainly, can approach it as a colour for scarlet geraniums, but its beauty is almost as fleeting as the flowers."

To this let me add, in the words of the same edition, "The palette wants weeding, not only of the bad new colours, but of the bad old colours. This, however, must be a work of time, and depend, not upon the colourman—for where there is a demand there will be a supply—but upon the artists themselves. To this end an increased acquaintance with the properties of pigments is required, whereby they may be able to choose the fast from the fugitive." To enable them to do so forms one of the chief objects of Field's work, and although naturalists, botanists, &c., are not, strictly speaking, artists, yet they so often have occasion to use colours that some knowledge of pigments would save them much trouble and annoyance. Allow me, therefore, to recommend to artistic science and scientific art a perusal of the "Chromotography."—I am, &c.,

THOMAS W. SALTER, F.C.S.

New Wandsworth, S.W.

MISCELLANEOUS.

Church's Laboratory Guide.—We understand that Professor A. H. Church's "Laboratory Guide" will shortly appear in an Italian translation, for use in the agricultural departments of the Royal Institute for Professional Education in the kingdom of Italy.

The Quality of the Gas Supplied to London.—Dr. Letheby, the Chief Gas Examiner appointed by the Board of Trade, has recently reported to the Corporation of London and to the Metropolitan Board of Works on the quality of the gas supplied by the Chartered, the Great Central, the City of London, the Imperial, and the South Metropolitan Gas Companies; from which it appears that the average illuminating power of the common gas has ranged from 15.68 standard sperm candles, in the case of the Imperial gas at the testing place at Camden Town, to 18.34 candles in that of the Great Central gas. The average quality of the gas at each of the testing places during the quarter has been as follows:—Great Central gas, at Friendly Place, 18.34 candles. City of London gas, at Cannon Street, 17.37. Chartered gas, at Leadenhall Street, 17.64; at Gray's Inn Lane, 16.93; at Arundell Street, Haymarket, 16.66. Imperial gas, at Chelsea, 16.29; at Camden Town, 15.68. South Metropolitan gas at Peckham, 15.90. The average quality of the Cannel gas has been 25.87 candles in the case of the City Company's gas, and 25.07 in that of the Chartered Company. As regards impurities, Dr. Letheby reports that the gas of all the companies has been constantly free from sulphuretted hydrogen, but that the amount of sulphur in other form than this has fluctuated to a very large extent, for while the average amount of this impurity was only 13.28 grains per 100 cubic feet of the City Company's Cannel gas, it amounted to 34.69 grains per cubic feet of the South Metropolitan gas. The average proportion of sulphur in the gas of each of the companies during

the quarter was as follows:—City Company's Cannel gas, 13.28 grains per 100 cubic feet; common gas, 21.84 grains. Great Central gas, 21.19 grains. Chartered gas, at Leadenhall Street, 22.97 grains; at Gray's Inn Lane, 27.87 grains; at Arundell Street, 28.45 grains. Imperial gas at Chelsea, 30.35 grains; at Camden Town, 24.03 grains. South Metropolitan, 34.69 grains. According to Dr. Letheby, these large differences are entirely due to the different processes of manufacture and purification, and they indicate the means of reducing this serious impurity to the smallest amount. Ammonia has not been present in excessive quantity in the gas of any of the companies except the Chartered, and it was only in excess in the gas of that company on the several days from the 12th to the 25th of July last, when it arose from accidental circumstances over which the company had no control.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Annalen der Chemie und Pharmacie, September, 1870.

This number contains the following original papers and essays:—

On Euxanthon and on Euxanthinic Acid.—A. Baeyer.—The author begins this lengthy memoir with an introduction on the employment of metallic zinc-dust for the purpose of withdrawing oxygen from aromatic compounds, and replacing it by hydrogen. Next, the statement is made that the nature and true constitution of euxanthon, first submitted to research by Dr. Stenhouse and the late Dr. Erdmann, is as yet very obscure. (Euxanthinic acid is a substance present in purrhee, Indian yellow; euxanthon is a derivative of that acid.) The author afterwards describes, at very great length, a series of experiments made with the view to elucidate the constitution, first, of euxanthon, which yields, when fused with caustic potassa, a new body, $C_{13}H_{10}O_6$, euxanthonic acid, distinguished from euxanthon by its far greater solubility in water, from which it crystallises readily. The formula of euxanthon, as originally put forward by Dr. Stenhouse—viz., $C_{12}H_8O_4$ —is considered by the author as true and correct, and also agrees with the products of substitution of euxanthon. A second portion of this memoir is devoted to euxanthinic acid, about which we meet with a lengthy discussion regarding the value of the formula assigned to this substance by various authors. According to the late Dr. Gerhardt, the formula of this substance is $C_{10}H_6O_3$; but, from a series of experiments, and from the substitution compounds of this acid, the author deduces the formula $C_{10}H_6O_{10}$.

Reduction of Aromatic Hydrocarbons by means of Iodophosphonium.—A. Baeyer.—This lengthy essay begins with a brief review of reduction experiments in general. Next, we meet with a description of a process for the preparation of iodophosphonium:—Dry sulphide of carbon is poured into a tabulated retort, and 100 grms. of phosphorus are dissolved in this liquid, to which, while kept very cold, are added gradually, and in small quantities at a time, 175 grms. of iodine. The sulphide of carbon is next driven off by gentle distillation, and the last traces of that liquid are removed by a current of dry carbonic acid gas, the retort being gently warmed all the while. When this operation has been finished, and the retort has cooled down, there is adapted to the retort, instead of the cooling tube, a rather wide tube, to which is fastened a gas-conducting tube, which ends in a bottle partly filled with water; but the tube should not touch that liquid. This having been done, there is placed in the tubulus of the retort, a funnel, the neck of which is drawn out into a long, narrow point. Through this funnel, a quantity of 50 grms. of water is gradually poured, by small portions at a time (this operation requires great care, since it may readily lead to very serious explosions). After all the water has been added, the retort is heated, at first gently, and at last to dull red heat, whereby the iodophosphonium is driven into the wide tube above spoken of. It condenses in the same, exhibiting a solid body resembling sal-ammoniac. The reaction described is expressed by $P_4I_4 + 2H_2O = PH_4I + PO_2$. The author further enters into exhaustive details on the best methods of making iodophosphonium react upon hydrocarbons, and the action of the former body upon benzol, toluol, xylol, meesitylen, naphthalene, and oil of turpentine is described at length.

Researches on the Bases of the Pyridine and Chinolin Series.—A. Bayer.—This monograph is divided into the following

sections:—Synthesis of picoline; preparation of picoline from acrolein ammonia; picoline from tribromallyl.

Aldehyde-Collidine.—E. Ador and A. Bayer.—This paper is really an integral portion of the preceding, but is in the original text under a separate title. Aldehyde-collidine is a body akin to the collidine obtained from Dippe's oil by Dr. Anderson. The authors have divided this paper into the undermentioned sections:—Action of iodethyl upon collidine; by-products of the preparation of collidine.

On Cinchonin-Chinoline.—N. Lubavin.—The author treats on Sulpho-chinolinic acid, $C_6H_4NSO_3$; tribrom-chinoline. It appears, from the author's researches, that chinoline belongs to the same series of bases as picoline and pyridine; but Dr. Bayer adds, at the end of this paper, that the true constitution of these bodies is as yet undetermined.

Vapour Densities of Acetic Acid.—A. Naumann.—This exhaustive monograph contains, in the tabulated form, the record of the following experiments:—Vapour densities at 78° , 100° , 110° , 120° , 130° , 140° , 150° , 160° , and 185° ; vapour densities of acetic acid for equal quantities of acetic acid in the unit of fluid measure; equal vapour densities of acetic acid for variable temperatures and pressures.

Aromatic Glycol.—E. Grimaux.—The author describes—Tollylen-chloride—

tollylen-bromide, $C_6H_5Br_2$; tollylen-iodide, $C_6H_5I_2$; monobenzoic acid tollylen-ether—

deuto-acetic acid tollyl-ether, $C_{12}H_{14}O_4 = C_6H_5(C_2H_5O_2)_2$; tollylen-glycol—

The Water of the Nile.—O. Popp.—The author states that, while staying in Egypt on a visit, he was requested by a Turkish prince, Halim by name, to make an analysis of the water of this celebrated river, the private chemical laboratory of the prince being placed at his disposal for this purpose. The author's paper opens with some particulars respecting the river Nile, which, from its source to its mouths (there are several), has a direct course of 4200 kilometres, by an average width of from 300 to 400 metres. The mean average temperature of the water of the Nile is only 20° or 3° below the average mean temperature of the air of Egypt. The sample of water taken for analysis was obtained from the middle of the river, some 6 miles below Cairo. Previous to being analysed, the water was left standing for two days, after which time the water was first filtered; but, even after this operation, it did not become quite clear, and it was found necessary, consequently, to leave it standing for some few days longer, when it deposited a flocculent sediment, which, on being tested, was found to consist of silica, a minute quantity of organic matter, lime, and magnesia salts. One litre of the water contains, in grammes: weight—Carbonic acid, 0.0346 ; sulphuric acid, 0.0030 ; silica, 0.0202 ; phosphoric acid, 0.00054 ; chlorine, 0.00337 ; peroxide of iron, 0.0036 ; lime, 0.0222 ; magnesia, 0.01467 ; soda, 0.02110 ; potassa, 0.00468 ; organic matter, 0.01720 —total, 0.14238 gm. Percentage composition of dry residue—Carbonic acid, 22.155 ; sulphuric acid, 2.755 ; silica, 14.150 ; phosphoric acid, 0.379 ; chlorine, 2.372 ; peroxide of iron, 2.227 ; lime, 15.640 ; magnesia, 10.332 ; soda, 14.852 ; potassa, 3.300 ; organic matter and small quantity of ammoniacal salts, 12.025 —total, 100.187 . Taking into consideration that the quantity of water annually carried by the Nile to sea amounts to 55,000,000,000 of cubic metres (equal to as many tons), some idea can be formed of the quantity of salts, &c., poured by this river into the Mediterranean. The author also analysed the mud and slime deposited from the water of the river; the composition of a sample taken at Soudan was, per centually—Peroxide of iron, 11.95 ; organic matter, 14.85 ; lime, 2.64 ; magnesia, 1.85 ; soluble silica, 5.50 ; clay and water, 62.3 .

Egyptian Trona.—O. Popp.—The substance known as trona (also named nitrum, although it does not contain even a trace of nitric acid or nitrates) is a native saline produce, a sample of which yielded, on analysis, per centually—Carbonic acid, 33.15 ; sulphuric acid, 1.65 ; chlorine, 5.11 ; soda, 36.34 ; lime, 0.55 ; water, 22.50 ; insoluble matter, 1.65 . Equal to—Sesquicarbonate of soda, 64.3 ; sulphate of soda, 1.5 ; chloride of sodium, 8.4 ; sulphate of lime, 1.3 ; water, 22.5 ; insoluble matter, 1.65 .

Composition of the Excrements of Egyptian Bats.—O. Popp.—After referring to the curious fact that Egypt, owing to its very clear sky at nights, and its sub-tropical climate, is especially suited for bats, of which no less than eight different genera are found there, the author proceeds to detail the methods of analysis at length; the result of the composition of the excrements, in 100 parts, being—Urea, 77.80 ; uric acid, 1.25 ; kreatine, 2.55 ; phosphate of soda ($2NaO.HO.PO_3$), 13.45 ; water driven off at 100° , 3.66 ; substances insoluble in water, 0.575 —total, 99.285 . In a foot-note to this paper, Dr. F. Wühler states that very recently the excrements of bats from Egypt have become an article of trade, as a sort of guano for manure purposes.

On Ceollipa.—F. Schickendantz.—By the name at the heading is understood (the pronunciation is koichpa) a saline efflorescence, not unfrequently met with in certain parts of the slopes and along the rivers originating in the Cordilleras de los Andes. The author gives, at great length, details of the analysis of several samples of this substance, which, setting aside impurities present only in small quantity, consists, in 100 parts, of—Soda, 45.21 ; carbonic acid, 25.99 ; water, 25.70 ; agreeing nearly with the formula $Na_2CO_3 + 2H_2O$. Another sample consisted mainly of—Water, 35.28 ; soda, 38.28 ; carbonic acid, 26.44 ; nearly agreeing with the formula $Na_2CO_3 + 3H_2O$. The author resides at Pucico, province of Catamarca, Argentine Republic.

Zeitschrift für Chemie von Beilstein, No. 14, 1870.

This number contains the following original papers:—

Ortho-Nitrotoluol.—F. Beilstein and A. Kuhlberg.—The authors describe—Nitric acid-metatoluolide, obtained by treating acetat-metatoluolide with a mixture of 2 parts, by bulk, of very strong fuming nitric acid (the so-called *acidum nitroso-nitricum*), and 1 part, by bulk, of strong nitric acid (sp. gr., 1.475). The product thus obtained is a solid, crystalline body, insoluble in water, soluble in alcohol, and fusing at about 197° . Ortho-nitro-metatoluolide, $C_7H_5(NO_2)O(NH_2)_m$, CH_3 , prepared from the preceding compound by decomposing it by means of dilute sulphuric acid or alcoholic solution of potassa; a solid yellow-coloured crystalline substance, soluble in alcohol, fusing at about 128° , and yielding no salts with acids.

Chlorinated Para-Chlorobenzoic Acid.—F. Beilstein and A. Kuhlberg.—*p*-Chlorobenzoic acid was treated in a sealed tube, at 200° , with 4 molecules of $SbCl_5$; and, after purification of the newly-formed substance, the authors found that the result of the reaction was the formation of di-chlorobenzoic acid.

On Xylol.—N. J. Tawildarow.—The author describes— β nitro-xylol; boils at from 237° to 239° ; fuses at 2° ; sp. gr. at 17.5° , 1.126 . β xylidine, and the oxalate of that base, of which latter salt 100 parts of water at 18° dissolve 3.319 parts. An acetyl derivative, $C_8H_7NH(C_2H_5O)$, from a xylidine, fuses at 123° , boils at 310° , and is very difficultly soluble in water. When crude xylol is treated with nitric acid, a series of nitro acids are formed; one among these yielded a barium salt, $(C_8H_7O_2)_2Ba + 2H_2O$ —that is to say, a new modification of tolyluic acid, which the author calls pseudo-tolylic acid.

Combination of Ethylen with the Bromides of Iron and Platinum.—C. Chojnacki.—The author gives, at great length, an account of the experiments by which he succeeded in preparing compounds of ethylen with iron and bromine, and also of the ethylen with platinum and bromine. The former combination, $C_2H_4FeBr_4 + 2H_2O$, contains, in 100 parts, 20 parts of iron, 57 of bromine, and 13 of water. The formula of the platinum combination is $C_2H_4PtBr_4KBr + H_2O$.

Researches on Sorbinic Acid, and on so-called Para-Sorbinic Acid.—J. Barringer and R. Fittig.—This lengthy memoir is divided into the following sections:—Action of hydrogen upon sorbinic acid, yielding hydro-sorbinic acid, $C_8H_{14}O_2$, a colourless, peculiar smelling liquid; sp. gr. at 19° , 0.966 ; boils at 204.5° ; is not solidified at -18° . Several of the salts of this acid are described. Action of bromine upon sorbinic acid.

Conversion of Piperonylic Acid into Protocatechutic Acid.—J. Remsen and R. Fittig.—This paper is chiefly a series of lengthy and complicated formulae.

Contribution to Our Knowledge on Oil of Rue.—A. Giesecke.—The author of this memoir first refers at some length to the labours of a large number of chemists on this subject. He next relates a series of his own experiments chiefly made with the view to settle the question regarding the true chemical oil of rue, which some consider to be a methyl-caprinol, $C_{11}H_{20} - CO - CH_3$. This view is confirmed by the author, who, moreover, has gone more deeply into this subject, treating on the action of nascent hydrogen on oil of rue, and the action of pentachloride of phosphorus on this substance.

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt, No. 2, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Contribution to Our Knowledge on the Dyas and Coal Formation in the Banate.—D. Stur.—The meaning of dyas is sometimes, and more usually, expressed by Permian; this latter term is derived from Perm, a large district of Russia, which is characterised by a peculiar formation of rocks. The contents of this paper chiefly relate to phuto-paleology—that is to say, a description of extinct plants found in the formations alluded to, situated in the Banate, a large district of Hungary.

Geological Studies Concerning the Orient.—F. Chevalier von Andrian.—This paper contains the detailed mineralogical description of various minerals composing the volcanic rocks bordering on the Bosphorus. The following chemical analyses made by M. Karl Ritter von Hauer, are quoted in this memoir:—Andesite, in 100 parts—Silica, 63.87 ; alumina, 15.76 ; protoxide of iron, 5.43 ; lime, 3.66 ; magnesia, 1.06 ; potassa, 3.33 ; soda, 3.59 ; loss by ignition, 2.05 —total, 98.75 . Greenstone, in 100 parts—Silica, 55.53 ; alumina, 13.81 ; protoxide of iron, 6.74 ; peroxide of iron, 4.45 ; protoxide of manganese, a trace; lime, 4.13 ; magnesia, 2.41 ; potassa, 3.64 ; soda, 3.26 ; loss by heat, sulphuric and carbonic acids, and water, together, 6.38 —total, 100.35 .

Trinkerite, a Newly-Discovered Fossil Resin.—Dr. G. Tschermak.—The author states that the resin alluded to is found in compact masses in the braunkohl formation, near Carpano and Albona, in Istria. The resin is brittle; its colour varies from hyacinth red to chestnut brown. The mineral exhibits a fatty gloss; is transparent; its fracture plano-conchoidal; sp. gr., 1.025 ; becomes highly electric when rubbed; gives off, on being gently heated, and also while being pulverised, an aromatic pleasant odour; its melting-point varies from 168° to 180° . When fused, the substance gives off a nasty pungent smell; and, when the molten mass begins to boil, vapours are given off, which, when carried into the substance of lead or copper salts, cause a black precipitate therein. This resin was chemically investigated by Professor Hlawetz, the result of whose research is as follows:—The substance is hardly soluble in alcohol or ether, but is perfectly soluble in boiling benzol; heated in a retort, it melts, begins to boil, then gives off sulphuretted hydrogen gas, and yields an oily distillate. The

elementary analysis led to the following percentage result:—Carbon, 81.1; hydrogen, 11.2; sulphur, 4.7; oxygen, 3.0; no ash. When treated with fusing caustic potassa, the resin is oxidised; but the products of this reaction did not yield anything specific. The resin appears to belong to the substances akin to copal; but the fact that it contains sulphur is peculiar, since as yet no other fossil-resin containing sulphur is known, except the tasmantite described by Dr. Church (*Phil. Mag.*, vol. xxviii., 1864, p. 465). The name of trinkerkite has been given to the substance alluded to in order to commemorate the discoverer, M. J. Trinker, geologist at Laibach. Although the composition of tasmantite (viz., carbon, 79.34; hydrogen, 10.41; sulphur, 5.32; oxygen, 4.93) is very nearly the same as the mineral just mentioned, the tasmantite is intimately mixed with from 60 to 70 per cent of clay (deducted, of course, in the analysis just quoted); and tasmantite, moreover, is altogether insoluble in benzol, Dr. Hlasiwetz having purposely tested this reaction with a specimen of tasmantite kept in the Imperial Mineralogical Museum at Vienna.

Bayerisches Industrie und Gewerbe Blatt, July, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Production of Cold by Mechanical Means.—C. Linde.—This lengthy memoir, illustrated by geometrical figures and a series of algebraical formulae, treats chiefly on the question of the amount of force to be applied in order to obtain the withdrawal of a certain amount of heat at a given temperature.

Description of an Apparatus for the Manufacture of Gas from Petroleum and from Residues left by the Distillation of that Liquid.—L. A. Riedinger.—This paper, illustrated by a series of exceedingly beautiful lithographs, contains the description of a well-arranged apparatus to produce gas from crude petroleum, or from the residues of its distillation. That industry has become rapidly developed on the Continent, as well as in the United States of America; and it is a wonder that it is not thought of in this country, the gas thus produced being far superior to coal-gas. The apparatus here alluded to is only contrived for use on a comparatively small scale (for 300 lights), but in many parts of Switzerland and Germany towns and villages are cheaply and effectually supplied with petroleum gas.

Revue des Cours Scientifiques de la France et de l'Etranger,
September 10, 1870.

This number does not contain any paper or memoir relating to chemistry or physical sciences, but it opens with a brief and modest eulogium on M. Jules Simon, the new Minister of Public Instruction, reminding, at the same time, that this gentleman was, on December 2nd, 1851, the most influential of the Professors of the Sorbonne, and a man who, in every respect, is eminently fit to be the head of the important public department just named.

Journal für Gasbeleuchtung, August, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Report of the Proceedings of the Tenth Annual Meeting of the Gas Engineers and Gas Works' Managers in Germany, held at Hamburg in the month of May last.—Dr. N. Schilling.—This report contains the following sections:—A paper on the establishment of an experimental gas work, to be constructed with the view of testing coals and making experiments on various matters of practical interest, the works to be the property of the Association. The experiments intended to be made are:—The accurate determination of the quantity of gas made from a given weight of coals after complete purification of the gas from sulphuretted hydrogen, ammonia, and carbonic acid. Determination of the specific gravity of the gas by the method of the velocity of efflux, as compared with atmospheric air; quantitative estimation of the heavy hydrocarbons contained in the gas, by means of absorption in the eudiometer; estimation of the illuminating power, according to a plan fully detailed by a sub-committee of the Association; estimation of the quantity of coke, by weight as well as by measure, care being taken to extinguish this material, when taken from the red-hot retorts, in a peculiar manner, without contact of air; estimation of the value of the coke as fuel; estimation of the value of the tar, and of the ammoniacal liquor, for various purposes.

Detection of Sulphur in Coal-Gas.—M. Ulex.—The author says:—The presence of sulphur in coal-gas can be proved in the following simple manner:—Let a platinum basin be filled with half a litre of water, and the basin be heated over a Bunsen burner until all the liquid has evaporated; the basin will be found to be coated, on the outside, where it has been struck by the flame, with a dirty, greasy looking substance, which, on being washed off with pure distilled water, and tested, proves to be sulphuric acid. The author further points out that the glass chimneys used with Argand gas-burners soon become coated over internally with a white substance, which, on being washed off with distilled water, will be found to be, on testing, sulphate of ammonia. The glass panes of a room wherein gas is burned for a few evenings consecutively will, when rubbed with the fingers of a clean hand, impart to it a substance which, on the hand being rinsed in distilled water, will yield a precipitate of sulphate of baryta with chloride of barium, and a brick-red precipitate with potassium-iodide of mercury.

September, 1870.

The original papers contained in this number do not, strictly speaking, relate to chemistry, but the titles of those which are of a more general practical interest are:—

Drainage considered in its bearing upon the Water Supply.—H. Speck.—This memoir contains some very interesting matters as regards the drainage of arable land and meadows, and the bearing thereof upon water supply.

Description of the Water-Works constructed in 1868 for the Supply of Good Potable Water to the City of Berne (Switzerland).—M. Rothenbach.—Illustrated with woodcuts.

Instructions, Rules, and Regulations concerning the Use of Gas and the Inspection of Gas-Works, Gas-Meters, and Gas-Pipes ordered to be observed by the Communal Authorities of Karlsruhe (Baden).—This paper is an excellent and brief epitome of, and guide for, gas managers, gas engineers, meter-makers, and gasfitters. It is a proof of the very great superiority of the technical instruction so generally spread over Germany; because, without sound knowledge no workmen could either understand or carry into effect what is here ordered to be done in the general interest of the whole community.

Pharmaceutische Zeitschrift für Russland, No. 1, 1870.

Since the beginning of this year this periodical has been published fortnightly, instead of monthly as before, but we have only just now received a portion of what has been published. The first number contains the following original papers and memoirs:—

Researches on the Fermentable Matter (Ferment Substanzen) contained in the Water of the River Newa, and in that of the Canals of St. Petersburg.—Drs. A. and F. Lysch.—This lengthy memoir contains the results of a series of experiments made with the view to ascertain, quantitatively, the presence of fermentable (that is, in this instance, "disease generating") matter which occurs in the waters above alluded to. The authors have, for this purpose, applied Schönbein's test, whereby the property of fermentable substances to decompose water is applied to the detection of the presence of these substances; while, moreover, the authors employed, for comparison's sake, a very weak solution of pure emulsion. The main result of these researches is chiefly of local importance to St. Petersburg only; but we learn that, while the water of the river Newa, even at the time of high floods, is comparatively very pure, and absolutely so in its normal state, the water of some of the canals contains a considerable quantity of fermentable matter.

No. 2.

On Ricinine and the Active Principle of Ricinus Seeds.—E. Werner.—After referring, at length, to Dr. Tuson's researches on this subject, the author describes a series of experiments, chiefly made with the view to obtain, from the ricinus seeds, an active principle suitable for medicinal use. As regards the ricinine of Dr. Tuson, prepared by the author in large quantity and according to Dr. Tuson's directions, it is stated that ricinine is not an alkaloid, and moreover, a substance which contains a considerable quantity of ash; and the author, after carefully made analysis, comes to the conclusion that Dr. Tuson's ricinine is a compound of magnesia and of an organic acid, the formula of this body being $C_{11}H_{20}O_{10}Mg_2 + 6H_2O$.

Japanese Firework Mixture.—O. Gürke.—The author recommends the following mixture:—Finely-pulverised nitrate of potassa, 70 parts; washed flowers of sulphur, 30 parts; *pulveris lycopodii*, 12 parts; beat and very light lamp-black, 8 parts. From 1½ to 2 grains of this powder are sufficient for use packed in strips of arable paper.

Occurrence of Naphtha and Ozokerite in Europe and Asia.—Dr. G. A. Björklund.—This lengthy memoir gives a detailed account of the enormous wealth of the Russian Empire as regards inexhaustible sources of naphtha and ozokerite, which latter is actually obtained by mining and quarrying in large quantities, and applied to the manufacture of paraffin, and, in some instances for the adulteration of bees'-wax.

No. 3.

Description of Various Pharmacognostic Substances met with in Central Asia.—Dr. R. Palm.—The author, a pharmacist residing at Taschkend (a large town situated at 43° 3' N. lat., and at about 68° E. of Greenwich), describes at length, and in a tabular form, a series of substances, a large number of which are known in Europe, but many being altogether unknown there even by name. As instances, we mention—*Baladiv*.—A drug somewhat akin in shape, size, and colour to large plums, but containing an oily fluid, and also a seed somewhat akin to the kernel of the almond; this drug is used as a dye material. *Scharium-Doris*.—The dried leaves of an unknown plant containing a large proportion of bromides and iodides, and yielding, with water, a thick mucilage; this leaf is imported from China. *Iriana*.—Small bitter-tasted seeds, containing a peculiar essential oil. *Akir-kava*.—A dry root imported from China, and very highly prized and expensive; is used as anti-scorbutic. *Kapnarz*.—A dirty violet-grey coloured powder; taste, strongly astringent; is used as a dye-stuff for producing black with sulphate of iron. *Scharatsch*.—A powder similar in appearance to rye-meal; it is used, after having been mixed with water, as paste, but also as cattle fodder, and is apparently the powder of an orchideous root. We cannot continue this lengthy catalogue; but it appears, from its contents, that the inhabitants of the Khokand are a far more civilised, and, also, industrially-developed, people than would appear to Europeans to be the case. Indeed, the

author of this paper states that these Tartars are acquainted, not only with drugs, dye-stuffs, and other substances entirely unknown in Europe, but also with industrial processes with which Europeans are not acquainted.

NOTES AND QUERIES.

Black Japan.—I shall be glad if you can tell me how to make the black japan that is used for coach work.—S. R. H.

Anthracene.—Will any reader of your valuable journal, inform me if there is any market for artificial anthracene, and what the price is?—H. J.

Hofmann's Violet.—(Reply to "Querist.")—You will find the reply to some, if not to all, of your queries in the work "On Aniline and its Derivatives," published by Longmans and Co., 1868.

Estimating Cyanides.—I should be glad of the best method of estimating the cyanides in brown sulphate of ammonia: the methods in the ordinary text-books, not being found satisfactory.—E. OUTHER.

Manufacture of Sulphuric Acid.—(Reply to "A Manufacturer.") In all probability the process you refer to is that of P. W. Hofmann, described in CHEMICAL NEWS, vol. xxi., p. 106, and also referred to in the same volume, p. 164.

Carbonic Ether.—(Reply to H. S.)—You will not be likely to buy this compound. According to the account given thereupon in the latest edition of the late Dr. W. A. Miller's work, "Elements of Chemistry," vol. iii., p. 225, it can be formed by heating argentic carbonate with iodide of ethyl, in a closed tube; but it is generally procured by heating sodium or potassium with oxalic ether.

Bleaching Wax.—(Reply to F. C. Terrell.)—The bleaching of bees'-wax and paraffin-wax (which is simply paraffin) cannot be effected by one and the same process. As regards the bleaching of bees'-wax, the description of that process is far too lengthy to be here detailed even in brief outline, and you had best consult on that subject Ure's "Dictionary of Arts, &c.," 6th edition, vol. iii., p. 1040. The same objection applies to paraffin, on which you will find an excellent article in the work just quoted, same vol., pp. 360 to 371.

Drying Oil.—(Reply to R.)—You wish for a good drying linseed oil, prepared without heat, by which is really understood that it is rendered drying without the usual process of boiling. Mix with old linseed oil, the older you can get it the better, 2 per cent of its weight of manganese borate (this salt is readily prepared by precipitating a solution of sulphate of manganese with a solution of borax, wash the precipitate, and dry it either at the ordinary temperature of the air or at 100°), and heat this mixture on a water-bath, or, if you have to work with large quantities, with a steam-bath to 100°, or at most 120°; you thus obtain a very excellent, light-coloured, rapidly-drying oil; by keeping the mixture stirred, that is to say, by always exposing fresh portions to air, the drying property of the oil is greatly promoted. The rapidity of the drying of the oil after it has been mixed with paint, on surfaces besmeared therewith, does not simply depend upon the drying property of the oil, but, in a very great measure, upon the state of the atmosphere—viz., whether dry or moist, hot or cold—the direct action of sunlight, and the state of the surfaces on which the paint is brought. Really genuine boiled linseed oil, if well prepared, leaves nothing to be desired as regards rapidity of drying, but it is retarded by various substances which are added in practice, among which, especially, oil of turpentine is injurious.

Hard and Soft Water.—(Reply to "Sanitas.")—Soft water does not necessarily imply rain-water; for instance, the waters supplied to Glasgow and Edinburgh are soft, and not, therefore, rain-water, in the sense you take it. The water supplied to the Metropolis becomes considerably softened by ebullition, on account of the precipitation of the carbonate of lime held in solution by carbonic acid, which escapes during the boiling. As regards drinking, we are inclined to think that, generally speaking, cold water is not too much used in the Metropolis, and what is used for that purpose is sufficiently soft and pure; indeed, the water supplied to some other towns of this country—e.g., Sunderland and South Shields—although very much harder than London water, is pleasanter and more refreshing to drink, on account of the far larger quantity of free carbonic acid contained in the water pumped up from deep wells bored into the rock. In many parts of Germany, especially in the province of Nassau, all spring water in ordinary use has a somewhat mineral taste, but its use does not injuriously affect the health of the inhabitants. The very pure water of the Rhine is not, in Germany at least, used for drinking or culinary purposes, unless by the shippers and crews of steamers and other vessels navigating that river.

TO CORRESPONDENTS.

J. Farie.—(1.) We know of no recent Chemical Catechism. (2.) *Keenan's* "Elementary Chemistry."

R.—Hardwich's "Photographic Chemistry," or Lake Price's work.

T. J. F.—Both your communications have been received.

R. Heaton.—(Received); thanks.

A. B. J.—The subject is a metaphysical one, which it would be a waste of time to discuss.

K. E. Lister.—You will probably get aureoline at Winsor and Newton's, Rathbone Place, W.

R. H. and Sons.—The work will not be ready yet.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations. Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations. Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 28s., 300 Illustrations. Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s. Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7, IRWILL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c., for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled *newly to double the size of his Laboratories*, and, at the same time, procure a large piece of ground which he has had laid out as a *Botanic garden*. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870–1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fees to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Polytechnic Institution, Regent Street.—EVENING SCIENCE INSTRUCTION.—Classes meet on the following Evenings:—Chemistry, on Tuesdays; Practical Chemistry, on Tuesdays; Electricity and Magnetism, on Thursdays; Acoustics, Light, and Heat, on Thursdays; Animal Physiology, on Fridays; Metallurgy, on Fridays. For Prospectuses apply to the Secretary, Mr. J. Cousens, at the Institution.

THE CHEMICAL NEWS.

VOL. XXII. No. 570.

SOLAR SPECTROMETRY.

REFERRING to Professor Young's spectroscopic notes published in our last issue, Mr. J. Norman Lockyer, F.R.S., writes to remind us that he saw sodium and magnesium prominences bright over sun spots a long time ago. The following appears in No. 5 of his "Spectroscopic Observations of the Sun," published in *Proceedings of the Royal Society*, No. 115, 1869, page 74:—

"Bright prominences, when seen above spots on the disk, if built up of other substances besides hydrogen, are indicated by the bright lines of these substances in addition to the lines of hydrogen. The bright lines are then seen very thin, situated centrally (or nearly so) on the broad absorption-bands caused by the underlying less-luminous vapours of the same substances."

NOTES ON A PROCESS FOR THE PRESERVATION OF BUILDING-STONES.*

By A. H. CHURCH, M.A.

My attention was directed to the subject of the preservation of stone about 1860. In 1862 I took out a patent for this purpose. The process consisted in the alternate application of solutions of pure baryta and pure (dialysed) silica. The plan was partially successful, and possessed the great advantage of causing no discolouration or efflorescence on the stone. But the solutions were rather weak, and, therefore, many repetitions of the process were necessary to secure an effective protection. Then, too, the silica solution failed to penetrate calcareous stone to any appreciable depth, owing to its rapid coagulation. After some years of further experiment, improvements were devised which ultimately resulted in a new and much more successful process. This process, for which a patent was obtained, in 1869, by Ransome's Patent Stone Company, consists in the successive and repeated application of three liquids. The first of these is a solution of mono-calcic phosphate, often erroneously termed biphosphate of lime, and first introduced, I believe, for a similar purpose, by Coignet. The second solution is one of barium-hydrate, applied warm if possible; and the third is a dialysed solution of silica, to which small quantities of the ordinary potassium and sodium silicates of commerce have been subsequently added.

It will not be necessary to dwell upon the proper methods of applying these solutions, nor upon the details of their manufacture. I may, however, mention that there is no difficulty in obtaining the various solutions in a state of sufficient purity and strength, and at a sufficiently low rate, to admit of their economical employment for the purpose in view. And it may be interesting to state that the dialysers employed, which are of the capacity of 6 gallons or more, and of an open bell shape, are found capable of doing their work very successfully when floated on or suspended in barrels of rain-water, or on rafts in a tank or pond; the movement of water below the diaphragm of vegetable parchment increases remarkably the rate of separation.

The reactions which take place between the several solutions themselves and between the solution and the constituents of the objects treated cannot be described in detail. The mono-calcic phosphate becomes

chiefly di-calcic phosphate in contact with a lime-stone, and then, on the application of baryta, a barium di-calcic phosphate is formed. If decay has already taken place, and sulphates have been formed in the stone, these are converted into insoluble and non-efflorescent barium sulphate, while the lime and magnesia thus liberated immediately become phosphated by the subsequent application of the mono-calcic phosphate solution. The siliceous solution finally employed keeps good some time, and penetrates some distance beneath the surface. It contains, indeed, a small quantity of alkalies, but their amount is not sufficient to produce any soluble salts in the treated stone or bricks. It would be tedious to enter into the proofs of this statement furnished by direct experiment. Extensive trials of the new process have been made on many important buildings, some of which have been entirely treated by the three solutions described above. I may cite as examples of the use of the process, the Chapter House at Westminster, and the St. Pancras Midland Terminus; portions of Canterbury Cathedral have also been submitted to treatment, together with numerous other buildings, public and private. Where the direction has been carried out with fidelity the results have invariably promised well. No marked alteration of the appearance of the stone is to be seen after the lapse of a few months from the time of using the process. The waterproofing of the stone effected by the use of the solutions is seen in many ways, particularly when after a shower of rain the colour of the treated surfaces is seen not to be darkened by absorption of water. A piece of black cloth drawn over a piece of Bath or Caen stone after treatment neither blackens the stone nor is itself whitened by it.

I may add, in concluding this very imperfect notice, that my process is one of those just selected (1870) for the renewed trial at the Houses of Parliament. The specimens exhibited are treated and un-treated specimens of the chief stones employed at the Chapter House, Westminster, and at the St. Pancras Terminus.

ON THE MAXIMUM OF MAGNETIC POWER EVOLVED BY A GALVANIC BATTERY.*

By the Rev. H. HIGHTON, M.A.

IN trying experiments on this subject, the author found that the magnetic power evolved by a given battery could be increased without limit. This was the case both in theory and practice.

Thus, if F = magnetic force of current in a unit of length of wire, E = electro-motive power, $R(b)$ = resistance of battery, $r(w)$ = specific resistance of wire, l = length of wire, s = section of wire—

$$F = \frac{E}{R(b) + r(w)\frac{l}{s}}$$

And if M = total magnetic force in the whole length of wire—

$$M = F \times l = \frac{El}{R(b) + r(w)\frac{l}{s}}$$

But if the length and section of the wire be increased in proportion, l becoming nl and s becoming ns , the equation becomes—

$$M = \frac{Enl}{R(b) + r(w)\frac{nl}{ns}} = \frac{Enl}{R(b) + r(w)\frac{l}{s}}$$

In other words, by simply increasing the length and section

* Read before the British Association, Liverpool Meeting, Section B.

* Abstract of a paper read before the British Association, Liverpool Meeting, Section A.

of the wire, the magnetic power may be increased without limit.

The experiment may be tried as follows :—

FIG. 1.

Let B be a galvanic battery, and m an electro-magnet supporting a weight of n lbs.

Change the arrangement as follows :—

FIG. 2.

Let B be the same battery, and m_1, m_2, m_3, m_4 be four electro-magnets exactly similar to the former one. Let half the current go through the magnets m_1 and m_2 , and the other half through m_3 and m_4 ; then it will be found that each magnet sustains $\frac{n}{2}$ lbs., or the whole four will bear $2n$ lbs., or twice the weight sustained before.

And the same process may be repeated or varied *ad infinitum*. Can we then get infinite power out of a finite source of force? Yes; but, on this condition, that what we gain in power we lose in time; for the current would take twice as long to traverse the second circuit, and, therefore, it takes double the time to produce double the magnetic power. But the electric current is so rapid that this difference of time is inappreciable within any practical limits.

It may be said that in this arrangement we are doing no work. This is so far true, that we are only doing work while the soft iron is being magnetised, and pressing the iron keeper to itself. But this work is being done every time that the circuit, after being broken, is closed; and the circuit may be broken and closed so many times a second that the number is practically illimitable, and hence the amount of work which can be done by a given battery is illimitable. The only question is a question of first cost of machinery.

What becomes of the electric power in the interval between the moment when the soft wire becomes fully magnetised, and the moment when the circuit is broken? It is wasted in producing heat in the wire,* and the smaller this waste the greater the available magnetic power.

All the relations given in our text-books between amounts of electrolysis, electric force, heat, and motion,

are true only partially and in particular cases. The author hopes, at some future time, to show how far they are true, and where they fail.

According to Joule, Favre, Silbermann, and others, the consumption of a gramme of zinc in a battery produces about 550 units of heat (each unit being able to raise about 423 grammes through 1 metre), or = about 232,650 grammes raised 1 metre. But Faraday said a grain of zinc produces more force than any flash of lightning; and Weber and Kohlrausch say that the force which decomposes 9 milligrammes of water—that is, the force of oxidation of 1 milligramme of hydrogen, can raise 208 tons 1000 metres! and a gramme of zinc will produce thirty times as much heat as a milligramme of hydrogen.

At a future time, the author will show the fallacies involved in all these calculations. Meanwhile, enough has been said to set aside the *a priori* argument against electro-dynamic engines—namely, that as a pound of zinc can only produce a certain amount of heat, and a pound of carbon, which is much cheaper, can produce more heat, therefore electro-dynamic engines can never compete with steam engines. In fact, it is a question of prime cost of machinery, and skill in construction, and not of cost of working.

ON THE CHEMICAL COMPOSITION OF THE BONES OF GENERAL PARALYTICS.*

By J. CAMPBELL BROWN, D.Sc.,

Lecturer on Chemistry and Toxicology at the Liverpool Royal Infirmary School of Medicine.

In consequence of the large share of public attention which has lately been attracted to the occurrence of fractures of the ribs among the patients in our lunatic asylums, several specimens of ribs of general paralytics have been sent to my laboratory.

The general appearance of all of them is so unlike that of the ribs of healthy adults, that I have been induced to submit average samples of them to analysis. In the accompanying table, the first four columns of figures show the composition of these samples.

I. Consisted of six ribs, which had all been fractured in a straight line downwards, and had completely united again by firm bony union; they showed slight callousities; some of them had again been fractured more recently, and had only imperfectly united; they contained an unusual amount of fat. Portions of the ribs were removed and were freed from fat before they were submitted to analysis, and the remaining portions were handed to the curator of the Museum of the Liverpool School of Medicine. The age of the subject from which they were taken was thirty-nine.

II. These ribs were not fractured, nor did they contain much fat; they were, however, thinner than usual. They were taken from the body of a patient who had suffered from mania with general paralysis.

III. Consisted of one rib only; it was slender and rough, and jagged on the edges, but had not been fractured. It was taken from the body of a woman aged forty.

IV. Shows the average proportions of organic and earthy matter in several samples not more completely analysed, which were remarkable only for being less perfectly developed than the ribs of healthy adults; some of these had been fractured and perfectly united, others were entire.

For comparison with these, I give the composition of the femur and tibia of a nine-months' foetus in column V., and of the bones from a case of osteo malacia in column VI.

VII. Is calculated from the analysis of a healthy adult tibia, by Valentin.

* Since writing the above, I have found strong reasons for doubting the truth of this statement; but I propose shortly publishing a full discussion of this point.—H. H.

* Read before the British Association, Liverpool Meeting, Section B.

VIII. Is calculated from the analysis of a healthy man, aged twenty-five, by Von Bibra.

Table of Analysis of Bones.

Constituents.	Ribs of General Paralytics.				V. Ninemoths, Fœtus.	VI. mal- acia.	VII. Tibia Adult (Valentin).	VIII. Ribs (Von Bibra).
	I.	II.	III.	IV.				
Phosphoric acid	23'52	28'85	19'09		23'31	16'89	24'24	25'95
Lime	29'57	28'54	25'25		28'98	22'20	32'98	34'43
Magnesia and alkalies.	0'41	0'43	0'37		0'36	1'05	1'37	1'67
Carbonic acid	1'55	1'29	2'09		1'10	1'71	3'37	2'90
Total inorganic constituents.	55'05	53'11	47'80	49'46	53'75	41'85	61'96	64'95
Organic con- stituents	44'84	47'02	53'05	50'54	47'15	58'16	38'02	33'97
	99'89	100'13	101'30	100'00	100'90	100'01	99'98	*98'92
Ratio of lime to 71 phos- phoric acid	89	88	93		88	92	97	94

It will be observed that the ratio of organic constituents to earthy matter is much greater, and also that the ratio of lime to phosphoric acid is distinctly less in the ribs of paralytics than in those of healthy adults.

There are the same differences between the composition of healthy ribs and those of paralytics as between the composition of the adult large bones and those of the fœtus. And, generally, the composition in cases of paralysis approaches that observed in cases of osteo malacia.

Whether the defects in the ribs of paralytics are due to arrested development, or to degeneration of the fully developed bone, it will require further experiments upon carefully selected cases to prove; but from the evidence already obtained, I am led to conjecture that both causes will be found to operate, but principally the former.

I exceedingly regret that more analyses have not been made before this time; it will be readily understood that specimens of bones cannot be made to order; we must wait until they can be obtained at *post mortems*; and I propose to continue the enquiry when more specimens have been obtained.

The result of the analysis quoted is suggestive, rather than conclusive, as to the condition of the bones in patients the subject of general paralysis, and it is clearly unsafe to generalise from a few examples. These analyses, however, form a first instalment towards determining whether the statements that have been made as to the peculiar liability to fracture of the bones in certain forms of insanity holds good as a general rule.

ON THE CALORIFIC POWER OF HARE'S BLOWPIPE.

By HENRY WURTZ.

OBSERVING in a lately received issue of the *CHEMICAL NEWS*, my first *partial* reply to Dr. W. M. Watts, I am encouraged to enclose a supplementary note in completion of said reply, lately printed by me in my own journal (*The American Gaslight Journal*). I perceive that Mr. Watts has also added a rejoinder to the aforesaid partial reply, which calls for a further continuation of the discussion on my part. I am gratified by the courteous tone of Dr. Watts's rejoinder, which I shall emulate.

Dr. W. M. Watts, in his strictures on the discussion of Professor Silliman and myself of the "Calorific Powers

or Effects of Gases," objects to our formula for the total heat of the oxyhydrogen flame, namely—

$$\frac{34462 - (9 \times 537^\circ)}{4'3245} = 6851^\circ;$$

remarking that "there is an error in assigning to liquid water the specific heat 0'4805, instead of 1. The formula should be—

$$\frac{34462 - 9 (637 - 48'05)}{4'3245} = 6743^\circ."$$

Dr. Watts's other points were probably sufficiently met in my reply, but this point was at that time expressly reserved, as looking to considerations which had already led to some little oral discussion between us, and with others.

Having had no opportunity, as yet, for that mature deliberation, in conjunction with Prof. S., that I desired to have, before going into print further on these questions of specific heat, and feeling that delay may cause misconstruction, I have given to them individually such consideration as I have had time for, and have decided to present a reply to Mr. Watts, in anticipation of our joint reply. In the preparation of the latter, arranged for an early day, any new lights that may appear in the interim, will of course be available.

Previous to the date of the first publication of our joint paper in the course of conversation with Prof. H. F. Walling, he made to me the suggestion that it was possible our formula ought to be so modified as to read—

$$\frac{34462 - 9 (537 + 51'95)}{4'3245} = 6743^\circ$$

leading, as will be seen, to the same figure as that of Dr. Watts. Prof. Walling, however, expressed himself as by no means *sure* of his view, as he had given no especial study to the subject, and offered it merely as an hypothesis. The apparent coincidence here gives more interest to the subject.

It is to be observed that Dr. Watts's formula supposes the temperature of the pound of hydrogen started with, in the combustion, to have been zero, and, further, that each of the nine pounds of water (as water) must have absorbed and retained 100° of sensible heat. Hence his figure 637°; which he diminishes, however, by 48'05°, for reasons which, as follows from the context, arise out of the difference between the specific heats of water and steam. The only conclusion I can draw from this is that Dr. Watts believes it requires an absorption of 51'95° of sensible heat from 1 pound of water at 100°, to convert it into 1 pound of steam at 100°, *plus* the 537° of latent heat generally admitted as the *actual result of experiment*; or, as may otherwise be stated, follows from Dr. Watts that the latent heat of steam at 100°, instead of 537°, is really 537° + 51'95° = 588'95°. I prefer as yet to stand by the experiment, until I receive from Dr. Watts some clearer explanation.

In the case of Prof. Walling, whose doubtfully submitted hypothesis also arose out of the consideration of the difference between the specific heats of water and steam, in the first place, it is clear at a glance, that the coincidence in the resulting figure is not accidental;

for $637 - 48'05 = 537 + 51'95$; and from this formula it is still more evident that, in addition to the 537° known by experiment to be all the heat that actually becomes latent in the conversion of one pound of water at 100° into one pound of steam at 100°, 51'95° more must be supposed to become latent, leaving but 48'05° of the sensible heat of the boiling water to remain sensible in the steam, and again increasing the latent heat of steam to the hypothetical number, 588'95°.

There must be a reason for every error (if this be one, as I cannot but conclude), as well as for every truth; and in seeking for the cause of this one, it seems to me to arise from a notion of specific heat, as absolute quantities, instead of mere *ratios*. The name is good, as it means

* This specimen also contained fat which had not been removed before analysis.

merely that different *species* of matter are differently affected by equal additions of heat; and specific heats are merely the ratios of these differences. When a body changes its state, as from water to steam, the 537° required to produce this change of state produces also a *change of specific heat*. The sensible heat remains unaltered. The 537° must come from external sources. Steam is different in species from water, and possesses a different specific heat ratio. Time fails for a fuller exposition of this subject now.

With regard to our formula for the total heat of Hare's blowpipe, though Dr. Watts's correction, as I have endeavoured to show, does not appear to me sustainable, there has occurred to me a small correction, necessary to precision, which I shall call attention to, here and hereafter, for the reason that the principle on which it depends, is, in its application to combustible gases, becoming now of practical importance. This is merely a correction for the temperature of the hydrogen before burning, which, for simplicity, Silliman and Wurtz assumed to be zero. If this temperature is the ordinary one of 60° F. (= 15.6° C.), at first glance it might appear necessary merely to add 15.6° to the 34462 in the numerator of our fraction. This would involve an error, however, which, though trifling here, would be very important in cases where the combustible or supporter of combustion is highly heated beforehand. Such cases I will discuss at an early day hereafter. Here I shall merely explain that in the oxyhydrogen flame, we must first calculate the mean of the specific heats of the gases in combustion, thus—

$$\frac{3.409 + (8 \times 0.2175)}{9} = 0.5721;$$

and we shall then have, instead of 7969°, the figure calculated, in our joint paper, by Silliman and Wurtz, a temperature differing so little therefrom as to be scarce appreciable—

$$\frac{34462 + 15.6 \left(\frac{1}{0.5721} \right)}{43245} = 7975°.$$

The explanation of the details of this calculation I must for the present defer.

LIME-LIGHTS IN THE CAISSON OF THE EAST RIVER BRIDGE.*

On page 190 of the last volume of the *CHEMICAL NEWS*, the fact was alluded to that arrangements had been made with the New York Oxygen Gas Co., to supply gas for a series of lime-lights by which the six compartments of this huge caisson might be lit.

We can now from personal inspection describe the arrangements by which some fourteen of these lights are kept in constant and successful operation. The plan of these adjustments is we understand, chiefly due to Mr. Martin, Assistant Engineer. To secure a steady supply of each gas under constant pressure, two large sheet-iron cylinders, about 21 inches in diameter and 6 feet high, are placed upon the top of the caisson, and are connected by iron piping with a water reservoir on the roof of an adjacent building, by which means a hydrostatic column or pressure of some 16 pounds per square inch is made available. These cylinders being filled with water, the gas is let into them from the portable cylinders supplied by the Oxygen Co., in which it is compressed up to a pressure of 225 pounds to the square inch. This displaces the water, forcing it back into the elevated tank and leaving only the tension due to its hydrostatic column of 32 feet.

Glass gauges exactly like those used on steam boilers show the level of the water in the stationary cylinders, and thus enable the attendant to regulate the supply of

* Communicated by Professor Morton. From advance-sheets of the *Journal of the Franklin Institute*.

gas in these, so as neither to overcharge them (when the excess would escape through the water-pipes and tank) nor allow them to become empty.

From the upper part of the gas reservoirs or stationary cylinders just described, service pipes are carried down into the caisson, and there distribute to the outer ends and middle points of each chamber where the usual jets and lime holders are permanently attached.

The light afforded by this means is excellent, and if it is possible (as we imagine it must be) to whiten the roof and upper part of the caisson walls, its efficiency would be very largely increased. In looking from one chamber of the caisson into another, where one of the lights was near the doorway but out of view, we were strongly impressed with the idea that daylight was entering through some unexpected opening. The foggy state of the air causes a considerable loss of light, so that at a distance from the burner this is less effective than one might expect. With the number of lights now in use, however, the supply is sufficient, and candles are only required in a few locations sheltered from the direct rays. We feel sure that a whitening of the roof and walls would be of very great service.

It is proposed to let the gas reservoirs descend as the caisson goes down, building around them a coffer-dam, by which means the hydrostatic head will be increased exactly as the air pressure in the chambers is raised, so that a constant difference will be maintained.

The greatest depth to be reached being 40 feet, the maximum pressure required, according to the present standard, would be about 36 pounds, and the pressure in the small charged cylinders being 225 pounds, no difficulty will be found in introducing the gas from them. The pressure now used is, however, largely in excess of what is required, as one or two pounds above that in the caisson would be quite sufficient to secure the steady burning of the lights. In fact, we are sure, from previous experience, that the pressure between the stop-cocks of the jets and the flames is now not more than a small fraction of a pound per square inch in excess of the surrounding compressed air. Were there any object in reducing it, we are quite confident that 25 pounds above the atmosphere would be an abundant pressure at the maximum depth of 40 feet.

The amount of gas now consumed is about 1200 cubic feet of each kind per day.

THE RISE AND FALL OF THE DEFUNCT ELEMENTS.*

By Dr. H. CARRINGTON BOLTON.

A COMPLETE catalogue of so-called "Defunct Elements," is nowhere found, but notices of their *rise* and *fall* are scattered throughout periodical literature; from these the following list has been compiled, which, if incomplete, is still comparatively full. Within the limits of this abstract, little more than the date, name of discoverer, and references can be given. Taking them up in chronological order, the first is

Terra Nobilis, discovered in 1777, by Tobern Bergmann, who extracted it from diamonds.

Hydrosiderum, discovered by Meyer, in 1780, and obtained by dissolving crude iron in acids, the residue being the new element. It is called in German *Wassereisen*. Klaproth showed that it consisted of iron combined with phosphorus. (*Schrift. Ges. Nat. Freund, Berlin*, ii., 334; and iii., 380.)

Saturnum, discovered in 1784, by Monnet. (*Journal de Physique*, xxviii.)

Diamanthspatherde, discovered in 1788, by Klaproth, in corundum. (*Beschäft. Ges. Nat. Freunde, Berlin*, viii., St. 4.)

* From the *Proceedings of the Lyceum of Natural History, New York*.

Australia, discovered in 1790, by Wedgwood, in sand from Australia, and examined by Hatchett, who pronounced it a mixture of alumina, iron oxide, silica, and graphite.

Nameless earth. Fernandez, 1799. *Scherer's Allg. J.* *Agusterde* was extracted from the mineral known as *silicische-beryll*, by Trommsdorff, in the year 1800. Vauquelin showed it to consist of phosphate of lime, the mineral being known as apatite. (*Scherer's Allg. J.*, iv., 312; also *Gehlen's Allg. J.*, i., 445.)

Silene, Proust, 1803. (*Journal de Physique*.)

Pneum alkali, discovered by Hahnemann in 1801. It was sold at the price of one gold Frederic the ounce, but eventually proved to be borax.

Niccolanum, was found in cobalt ores by Richter, in 1805, but was shown to consist of a mixture of nickel, cobalt, arsenic, and iron. (*Gilb. Ann.*, xix, 377.)

Andronia, an earth which existed only in the imagination of J. J. Winterl, of Pesth. He prepared it by igniting charcoal with saltpetre and exhausting with water, the residue consisting of *andronia*. His statement excited much controversy; a committee of the French Academy of Sciences appointed to examine it, proved that it was but a mixture of lime, alumina, iron oxide, and silica, which materials, it was suggested, came from the earthen crucibles in which Winterl conducted the experiments. (*Gehlens J. und Gilberts Annalen*.)

Thelike, discovered by Winterl.

Nitricum, is the imaginary body, which, according to Berzelius, united to oxygen formed nitrogen.

Aræon, is in accordance with Meissner's views, *ponderable caloric*; thus hydrochloric acid is composed of two equivalents of oxygen and one of water, combined with aræon and the imaginary radical murium. (*Handwörterbuch*.)

Junonium, discovered by Thomson, in 1811, but its identity with cerium was soon proved by Wollaston. (*Phil. Mag.*, xxxvi., 278; also *Gilb. Ann.*, xliv., 113.)

Thorium; the first element known by this name, proved to be phosphate of yttria. (*Schweigg.*, xxi., 15; *Pogg. Ann.*, iv., 145.)

Vestium, discovered in 1818, by von Vest. Faraday showed that it consisted of a mixture of iron, nickel, sulphur, and arsenic. (*Gilb. Ann.*, lix, and lxii.)

Wodanium, extracted from the so-called *Wodankies* by Lampadius, 1818, but shown by Stromeyer to consist of nickel, arsenic, &c. The mineral is now known as Gersdorffite. (*Gilb. Ann.*, lx, and lxiv.)

Crodonium, discovered by Trommsdorff in 1820, was found in an incrustation, on a carboy of sulphuric acid imported from England. Its name is derived from *Crodo*, an idol held in veneration by the ancient people of Thuringia. Trommsdorff afterwards showed that it was but lime and magnesia, rendered impure by copper and iron. (*Gilb. Ann.*, lxv. and lxvi.)

Apyre, Brugnatelli, 1821. (*Gilb. Ann.*, lxvii.)

Pluranium, *Polinium*, and *Ruthenium*, all three discovered by Osann (1828), in platinum ores from the Ural Mountains. (*Pogg. Ann.*, xlii. and xiv.)

Donium, discovered in 1836, by Richardson, in a mineral from Aberdeen, but its identity with glucinum was afterwards established by Heddle. (*Ann. Chem. Pharm.*, xix, and xxiii.)

Treenium, discovered by Boase, in 1836, and partly supposed identical with donium. (*Thomson's Records Gen. Sci.*, iv., 20.)

Terbium, found accompanying erbium in gadolinite, by Mosander (1843), but pronounced by Berlin (1860), to have no existence. (*Ann. Chem. Pharm.*, lxxviii., cxxxi., cxxxvii., &c.)

Pelopium, discovered by Rose, in 1846, and supposed to accompany niobium (columbium). Rose has shown that pelopic acid is convertible into niobic acid, and this into hyponiobic acid. (*Pogg. Ann.*, lxxix. and xc.)

Ilmenium, discovered in 1846, by Hermann. (*Fourn. Pr. Chem.*, xxxviii. and xl.; also *Pogg. Ann.*, lxxiii.)

Aridium, discovered in 1850, by Ullgren. (*Fourn. Pr. Ch.*, lii.; *Ann. Ch. Pharm.*, lxxvi. and lxxviii.)

Donarium, discovered in 1851, by Bergmann. (*Ann. Ch. Pharm.*, lxxx. and lxxxiv.)

Thalium, discovered in 1832, by Owen. (*Am. J. Sci.*, (2) xlii., xvi., and xvii.)

Nameless metal of platinum group, discovered by Genth, in 1853. (*Am. J. Sci.*, (2) xv.)

Dianum, extracted from tantalite from Finland, by von Kobell, (1860). H. Rose questioned its identity, also Sainte-Claire Deville and Hermann. Von Kobell distinguished it from niobic and tantallic acids, by the formation of a deep blue solution, when treated with tin and hydrochloric acid. (*Ann. Ch. Pharm.*, cxiv., and cxxxvi.)

Wasium, discovered by Bahr, in 1862. (*Pogg. Ann.*, cxix., 572; *Fourn. Pr. Ch.*, xci., 316.)

Nameless earth of the calcium group, Dupré, 1861.

Nameless metal of platinum group, Chandler, 1862. (*Am. J. Sci.*, (2) xxxiii.)

Yargonium; under this head are collected the various oxides supposed to accompany zirconia; it appears that six chemists have independently suspected the compound nature of zirconia, as follows:—

- | | | | |
|------|-----------------------|----------|--------------|
| (1.) | <i>Norium</i> | in 1845, | by Svanberg. |
| (2.) | <i>Nameless earth</i> | in 1854, | " Sjögren. |
| (3.) | <i>Nameless earth</i> | in 1864, | " Nylander. |
| (4.) | <i>Nigrum</i> | in 1866, | " Church. |
| (5.) | <i>Yargonium</i> | in 1869, | " Sorby. |
| (6.) | <i>Nameless earth</i> | in 1869, | " Loew. |

The references are as follows:—

- (1.) *Bers. Jahresb.*, xxv.; *Fourn. Pr. Ch.*, lvii. and xcvii. (2.) *Fourn. Pr. Ch.*, lv. and lvii. (3.) *Acta Univers. Lundensis*, 1864. (4.) *CHEM. NEWS*, 1869. (5.) *Idem*. (6.) *Annals. N. Y. Lyc. Nat. Hist.*, ix., 211.

Summing up all the reactions by which these unknown oxides are distinguished from zirconia we have the following table.

- (1.) Great variation in atomic weight of oxide. Svanberg.
(2.) Solubility of oxide in oxalic acid.

Svanberg, Sjögren, Loew.

- (3.) Solubility of chloride in hydrochloric acid.

Svanberg and Forbes.

- (4.) Precipitation by ferrocyanide of potassium. Sjögren.
(5.) Insolubility of tartrate in tartaric acid. Forbes.
(6.) Solubility of double potassium sulphates. Nylander.
(7.) Variation in nature of sulphates. Loew
(8.) High. sp. gr. of oxide (5.5 instead of 4.3). Sjögren.
(9.) Black absorption bands of spectrum. Church, Sorby.

(2.) Some misapprehension exists on the second point, owing to the fact that most text-books state that zirconia is *insoluble* in oxalic acid, whereas, Berlin, in 1853, showed, on the contrary, that zirconia is readily and completely *soluble* in oxalic acid.

In Finkener's revised edition of H. Rose's work, the error contained in earlier editions is corrected.

(8.) Berlin found the sp. gr. of zirconia from catapleite = 4.9, precisely the mean of the other two.

(9.) The manner in which Sorby has explained the last point is familiar to all.

Preparation of Barium Chlorate.—Brandau has proposed the following simple method for the preparation of barium chlorate:—Commercial crystallised aluminium sulphate, sulphuric acid, and potassium chlorate, in the ratio of one molecule of each of the two former to two of the latter, are mixed with water to the consistence of a thin paste, warmed for half an hour on the water-bath, allowed to cool completely, and treated with alcohol in excess. Upon filtering, and neutralising with barium hydrate, barium sulphate and some aluminium hydrate are precipitated, and barium chlorate remains in solution. The alcohol is distilled off, and the filtrate on evaporation yields crystals of the pure barium chlorate. The only precaution necessary is to have the aluminium sulphate and the sulphuric acid in slight excess.—*Ann. Ch. Pharm.*, cli., 361. *Am. Journ. Sci.*, No. 148.

ON THE
PRECIPITATION AND DETERMINATION
OF THE

METALS OF THE MAGNESIUM GROUP IN
THE FORM OF OXALATES.

By W. GOULD LEISON.

PROFESSOR GIBBS has recently* called attention to the fact that a number of metallic oxides may be completely precipitated from their neutral solutions by means of oxalic acid, provided that a large excess of alcohol be also added. As it is not easy to obtain precise quantitative results by igniting the oxalates so precipitated, in consequence of the extreme subdivision of the resulting oxides, Professor Gibbs suggested the employment of potassic hypermanganate for the combustion of the oxalic acid—a method which, as is well known, gives excellent results in the case of calcic oxalate precipitated in the ordinary manner. The following investigation was undertaken for the purpose of testing this method of analysis:—

Cadmium.—Cadmic sulphate was dissolved in the least possible quantity of water, oxalic acid added in excess, and then a large quantity of strong alcohol. The resulting oxalate was beautifully crystalline, and the precipitation was so complete that SH_2 gave, in the filtrate, a scarcely perceptible yellowish tinge. The oxalate was washed with alcohol by Bunsen's method, and dried at 110°C ., until every trace of alcohol was expelled. The filter was then pierced with a glass rod, and the cadmic oxalate washed into a flask with hot diluted sulphuric acid. A few cubic centimetres of strong sulphuric acid were then added, and the hot solution titrated with potassic hypermanganate. In this manner, four experiments gave 44.19 per cent, 44.65 per cent, 44.88 per cent, and 44.27 per cent of cadmium, as computed from the oxalic acid. These results are all much too high, and show that the acid had acted sensibly upon the filter. Two other experiments were then made. In the first, a hot solution of ammoniac sulphate was used as a solvent for the oxalate; in the second, hot dilute chlorhydric acid was employed. Of the hypermanganic solution employed, 100 c.c. contained 0.1103 gr. of available oxygen.

- I. 0.4330 gr. cadmic sulphate required 24.5 c.c. hypermanganate = 43.68 per cent Cd.
- II. 0.3724 gr. cadmic sulphate required 21.1 c.c. hypermanganate = 43.74 per cent Cd.

The received formula, $3\text{CdSO}_4 + 8\text{H}_2\text{O}$, requires 43.75 per cent. In these two analyses the filters were not broken.

Barium.—Baric chloride gave extremely variable results in my first experiment, notwithstanding the fact that the barium is completely precipitated by oxalic acid and alcohol. The resulting oxalate, after washing and drying, was not completely decomposed by sulphuric acid, which appeared to form a crust of baric sulphate upon the crystals of the oxalate. This difficulty was finally overcome by dissolving the baric oxalate in chlorhydric acid and diluting the solution largely. In this manner—

0.6505 gr. baric chloride required 80 c.c. hypermanganate = 56.21 per cent Ba (100 c.c. hypermanganate solution contained 0.053 gr. available oxygen). The formula $\text{BaCl}_2 + 2\text{H}_2\text{O}$ requires 56.15 per cent Ba.

Strontium.—To avoid the use of paper filters, so as to be able to employ sulphuric acid as a solvent, I resorted to sand filters. A light funnel was ground truly conical near the throat; a little pear of glass with a long stem was then dropped into the funnel, stem upward. In this manner, a valve was formed impassable to the sand laid upon the ball of the glass, but allowing liquids to pass freely. By means of the stem, the valve could be lifted

from its seat, and the sand and precipitate washed together into a flask, after careful drying. With this arrangement:—

0.4292 gr. strontic nitrate required 47.8 c.c. hypermanganate = 48.90 per cent SrO.

0.3657 gr. strontic nitrate required 40.8 c.c. hypermanganate = 48.90 per cent SrO. (100 c.c. hypermanganate solution contained 0.1099 gr. available oxygen.)

The formula $\text{Sr}(\text{NO}_3)_2$ requires 48.93 per cent SrO. Sulphuric acid only was used to decompose the oxalate.

Calcium.—Iceland spar was dissolved in chlorhydric acid, and the solution treated with oxalic acid and alcohol. The filtrate contained calcium. When, however, the solution was evaporated to dryness before adding alcohol, and the oxalate was washed on a sand filter, no traces of calcium could be detected in the filtrate. In this manner—

0.5090 gr. CaCO_3 required 70.6 c.c. hypermanganate = 56.10 per cent CaO. (100 c.c. hypermanganate corresponded to 0.11559 gr. oxygen.)

0.5590 gr. CaCO_3 required 77.5 c.c. hypermanganate = 56.08 per cent CaO. (100 c.c. hypermanganate corresponded to 0.11495 gr. oxygen.)

The formula requires 56.00 per cent CaO. Sulphuric acid only was employed.

Magnesium.—When magnesian sulphate is treated with oxalic acid, the mixture evaporated (but not to dryness), and alcohol added, the filtrate is perfectly free from magnesium. In this manner—

0.3243 gr. $\text{MgSO}_4 + 7\text{H}_2\text{O}$ required 39.6 c.c. hypermanganate = 16.18 per cent MgO.

0.3949 gr. $\text{MgSO}_4 + 7\text{H}_2\text{O}$ required 48.4 c.c. hypermanganate = 16.25 per cent MgO.

In these analyses, the oxalate was collected on a paper filter, and washed into the flask with water after piercing the filter, which was washed with cold dilute sulphuric acid. The formula requires 16.26 per cent.

Zinc.—Zinc is completely thrown down from its sulphate by the unmodified process. The oxalate forms an extremely fine powder. A sand filter and warm dilute sulphuric acid were employed.

0.9301 gr. sulphate required 47.1 c.c. hypermanganate = 28.14 per cent ZnO.

1.0788 gr. sulphate required 54.6 c.c. hypermanganate = 28.15 per cent ZnO.

The formula requires 28.22 per cent ZnO.

Cobalt.—Perfectly pure anhydrous cobaltous chloride was prepared by igniting chloride of purpureo-cobalt. The chloride was then precipitated by oxalic acid and alcohol, collected on a sand filter, and digested with dilute sulphuric acid. The solution was intensely red. A solution of nickeliferous sulphate was then added, until the red colour disappeared and a faint smoky hue took its place.* In this manner—

0.4292 gr. CoCl_2 required 47.8 c.c. hypermanganate = 45.30 per cent Co.

0.3657 gr. CoCl_2 required 40.8 c.c. hypermanganate = 45.37 per cent Co.

The formula requires 45.38 per cent (Co = 59).

Nickel.—In the case of nickeliferous sulphate, it was found necessary, after adding the oxalic acid, to concentrate the mixture on a water-bath before adding alcohol, and then further digest for about half an hour, replacing the alcohol as fast as it evaporated. The oxalate was collected on a paper filter, and, after washing, dissolved in ammonia on the filter. The filtrate was then acidified

* Amer. Journ. Sci., vol. xlv., p. 213.

* Compare, as regards this method, W. Gibbs, Amer. Journ. Sci., vol. xiv., p. 204.

with sulphuric acid, and the colour finally discharged by a solution of cobaltous sulphate. In this manner—

0.9585 gr. nickeliferous sulphate required 42.2 c.c. hypermanganate = 28.57 per cent NiO.

1.0287 gr. nickeliferous sulphate required 45.3 c.c. hypermanganate = 28.58 per cent NiO.

The formula $\text{NiSO}_4 + 6\text{H}_2\text{O}$ requires 28.24 per cent NiO (Ni = 58), but it is very difficult to obtain the sulphate in a perfectly definite state of hydration.

Manganese.—Although manganese is completely precipitated from its soluble salts by oxalic acid in the presence of alcohol, my results with the method have not been satisfactory, owing, as I suppose, to my not having a definite salt for analysis. The following analyses show, at any rate, that closely corresponding results can be obtained when the same substance is taken:—

0.3760 gr. manganous oxalate required 30.50 c.c. hypermanganate = 38.38 per cent MnO.

0.4013 gr. manganous oxalate required 32.55 c.c. hypermanganate = 38.38 per cent MnO.

The salt $2\text{C}_2\text{MnO}_4 + 5\text{H}_2\text{O}$, when dried in air, requires 37.77 per cent MnO, while the salt analysed was dried at 100° C. In like manner, two analyses of a sulphate, which had probably absorbed a little water, gave 45.28 per cent and 45.29 per cent of MnO. The crystallised sulphate, $\text{MnSO}_4 + 7\text{H}_2\text{O}$, requires 46.67 per cent.

Iron.—Good results could not be obtained by the application of this method to the determination of iron, but I am not at present able to assign the reason of the failure in this case.

To complete my work, it remains for me to point out the applicability of the process to the determination of the whole quantity of oxygen contained in a number of bases present together in solution—a problem which is sometimes of interest.

Sulphates of manganese, magnesium, nickel, cobalt, cadmium, and zinc, in undetermined quantities, were dissolved together in water, and the solution well shaken. Four portions, of 100 c.c. each, were then taken, and the acid determined in each by baric chloride. In two other equal portions, the bases were precipitated as oxalates and titrated as above. The oxygen in the acid was then calculated from the amount of baric sulphate. In this manner it was found that the oxygen in the acid was, to that in the mixed bases, as 3 to 1 very nearly, the precise ratio being, in the one case, as 0.054 is to 0.018, and in the other as 0.055 is to 0.018. Another experiment was made with a crystallised dolomite containing 0.45 per cent of insoluble residue. The lime, magnesia, and iron were precipitated together, and titrated as oxalates; the carbonic acid was determined by ignition. In this manner, the oxygen of the acid was found to be, to the oxygen in the bases, as 34.48 is to 17.28. The bases, after ignition, amounted to 52.41 per cent.

In another experiment with a dolomite from a different locality, containing 0.13 per cent of insoluble residue, the oxygen ratio was found to be as 34.56 is to 17.28, the bases amounting to 52.33 per cent. If we calculate the relative quantities of calcic and magnesian carbonates from the sum of the two oxides in the last analysis, and the oxygen found by titrating the oxalate, we find—

MgCO_3	42.77
CaCO_3	57.07
Insoluble residue	0.13

99.97

The small quantity of ferrous oxide present being neglected. This analysis will serve to show the applicability of the method in indirect analyses. My results appear to me to furnish a generalisation of the use of potassic hypermanganate, which will be received with favour by those who employ this reagent frequently in volumetric analyses.

DESCRIPTION OF A GAS FURNACE FOR CHEMICAL OPERATIONS AT A WHITE HEAT, WITHOUT THE AID OF A BLOWING MACHINE.

By CHARLES GRIFFIN.

Fusions at a white heat can be readily effected by a gas furnace supplied with air by a blowing machine. But a furnace of that description has several defects:—The blowing machine is expensive; it is cumbersome in a laboratory; it demands constant labour during a fusion;

FIG. 1.

and it produces so much noise as to interrupt every kind of quiet work.

The furnace to be described in the following notes is free from these defects. It is small and portable, easily put together and taken asunder. It demands no blowing machine, and only a small chimney. It acts without smoke, or dust, or noise. Its heating power is sufficient to raise a 44-inch clay crucible, filled with metal, to a

white heat. Cast-iron can be fused in it and cast into ingots of the following weights:—

A. Commencing with the furnace cold—

An ingot of 2 lbs. in 70 minutes.

An ingot of 3 lbs. in 90 minutes.

An ingot of 4 lbs. in 2½ hours.

B. Commencing with the furnace hot—

An ingot of 2 lbs. in 40 minutes.

An ingot of 2½ lbs. in 50 minutes.

An ingot of 5 lbs. in 2½ hours.

Silver, gold, and copper can be fused in larger quantities and in less time.

The furnace is represented by Fig. 1. Its height, including the stool, is about 2 feet. The external diameter is 8 inches. It consists of the following parts:—

a is a brass cylinder, open at the bottom, and into the top of which sixteen Bunsen's burners are fixed; gas is supplied by the pipe, *b*, regulated by the stop-cock, *c*. A jacket surrounds the upper part of the Bunsen's burners, but is cut away at the bottom, *d*, in order to permit air to pass up between the burners.

The consumption of gas by this compound burner when at work in the furnace is 33 cubic feet per hour.

e is an iron stool, which supports the furnace and also the iron rod, *k*, to which the chimney is attached.

f is a fire-clay sole plate, shown in section by Fig. 2. The system of burners is closely fixed in the perforation of this plate.

FIG. 2.

g is a cylinder of fire-clay, shown in section by Fig. 3. It measures 6 inches in height, 8 inches in external diameter, and 5 inches in bore. The crucible to be heated is supported on a perforated plumbago cylinder, represented in section by Fig. 3, and in perspective by Fig. 4. In

FIG. 3.

FIG. 4.

order to secure the greatest degree of fusing power, the bottom of the crucible, *c*, Fig. 3, should be fixed at 1-inch or 1½-inch distance from the face of the bundle of gas-burners, *a*, Fig. 1. For this purpose, the two plumbago cylinders supplied with the furnace differ ½ inch in height.

The crucible must be conical, not barrel-shaped, in order that the flame, after striking the crucible, may have space to escape through the holes in the plumbago cylinder.

The distance between the outside of the plumbago cylinder and the inside of the furnace cylinder, that is to say, the space marked *s, s*, in Fig. 3, must not exceed ½ an inch all round. Increase of space here lessens the heating power of the furnace.

h, Fig. 1, is the dome or roof of the furnace. It is represented in section by Fig. 5. This figure shows that the

FIG. 5.

flame, in rising from the body of the furnace, is bent twice at a right angle before it passes into the chimney.

i, i, Fig. 1, is an iron chimney, which measures 4 feet in length, and 2 inches in diameter; *k* is a vertical iron rod, screwed into the stool, *e*, of the furnace at *l*. This chimney is movable by the handle, *m*. At *n* there is a guide, and at *o* a stop. By this arrangement the chimney

can be set on the furnace, or moved aside, with facility. This movement is sufficient when the furnace is used for simple fusions, or when no deleterious gases are driven off; but when arsenic, sulphur, &c., are expelled during an operation, and the entire apparatus cannot be placed under a hood or fixed chimney, then the upper end of the chimney, *i, i*, should be passed into the vertical branch of a knee-piece, the horizontal branch of which is connected with a fixed flue, and the chimney, *i, i*, should be raised within the knee-piece by moving upwards the stop, *o*, on the rod, *k*. A rise of about 6 inches is necessary to make room for the removal of the dome, *h*, and the cylinder, *g*, on dismantling the furnace to remove a crucible. It is necessary to see that the draught of the fixed chimney is not too powerful.

The method of mounting crucibles exhibited by Fig. 3 serves for 4½ inch and for 4 inch crucibles, but not for smaller sizes. A 3 inch crucible slips through the plumbago cylinder and spoils the draught, and if a smaller cylinder is used, the spaces, *s s*, Fig. 3, become so wide that the effective heat of the furnace is greatly diminished. Hence it is necessary, when small crucibles are to be used, to support them on a grate made of fire-clay, the best form of which is represented by Fig. 6. Its diameter is

FIG. 6.

FIG. 7.

6 inches. This grate is placed upon the sole plate of the furnace. The crucible is set upon it, and is surrounded by a smaller fire-clay furnace cylinder, namely, by one that measures 5 inches in height, 6 inches in external diameter, and 4 inches in bore. The dome, Fig. 5, or *h*, Fig. 1, is used with the small cylinder, Fig. 7, as well as with the large cylinder, Fig. 3.

Platinum and porcelain crucibles can be heated in the small furnace, Fig. 7, enclosed in fire-clay crucible cases.

The fire-clay grate, Fig. 6, can be used with the large cylinder, Fig. 3; and, in crucibles supported by it, as much as 3 lbs. of cast-iron can be melted; but the operation requires an extra half-hour of ignition beyond that required when the crucible is supported by the plumbago cylinder, Fig. 4.

When the furnace is mounted for use with the large cylinder, Fig. 3, three bronze pennies are put on the sole plate, *f*, Fig. 1, to support the cylinder, *g*; when the grate is used, the three pennies are put under the extreme edge of the grate. These pennies leave a space for the admission of air.

Operations that succeed at moderate temperatures, such as the fusion of zinc in an iron pot or ladle, are performed without using the dome and chimney. The vessel to be heated is to be placed on the inner cylinder of Fig. 3.

The furnace body, Fig. 3, and the dome, Fig. 5, are provided with iron handles. These never become very hot, not even when the furnace contains 3 lbs. of melted iron. The operator's hands are sufficiently protected when lifting these pieces by a couple of folds of thick cloth, or brown paper. The small cylinder, Fig. 7, is handled by the same bow tongs that serve to lift the hot crucibles.

Access to the crucible in the furnace is gained at any moment by turning aside the chimney, and lifting the dome, *h*, Fig. 1. When the crucible is to be removed, the dome is first taken from the furnace, and placed on a circular plate of fire-clay; the outer cylinder is next lifted off, and placed on a similar plate of fire-clay. The crucible can then be removed by the bow tongs. If the furnace is to be immediately used for a second operation, the

cylinder should be covered with a third clay plate, to retard the loss of heat while the crucible is being replaced by another.

GAS MUFFLE FURNACE.—When the furnace cylinder, *g*, Fig. 1, is replaced by an oval furnace body that contains a muffle, as represented by *m* in Fig. 8, all other

Fig. 8.

Fig. 9.

parts of the furnace remaining as represented by Fig. 1, the usual muffle operations can be performed, such as cupellation, the roasting of ores, the combustion of organic bodies for their ashes, the burning of filters, &c. The muffle belonging to this furnace measures 7 inches in length, 3½ inches in width, and 2½ inches in height. It requires a bright red heat, sufficient to melt silver, gold, and copper. This heat can be kept steady and uniform for hours; and being free from dust or soot, is particularly suitable for such operations as annealing.

Nothing new is offered in the burner of this apparatus, for it is merely a bundle of Bunsen's jets; nor in the fire-clay fittings, which are copied from Griffin's Blast Gas Furnace; but a few words may be said on one or two other points.

The first relates to the supply of gas and air. The greatest heat is produced when coal-gas is burnt in the presence of as much air as entirely decomposes and oxidises it; that is to say, when one volume of gas is mixed with ten or twelve volumes of air; but when gas is mixed directly with so large a quantity of air, it becomes explosive, and cannot be used as fuel. It is consequently necessary, in the management of a gas furnace, to supply the air, certainly as rapidly as the combustion demands, yet so gradually as to avoid explosions. In arranging the furnace now under discussion, the gas is supplied in excess, and the air in three successive doses:—the first quantity at the bottom of the cylinder, *a*, Fig. 1; the second at the openings, *d*, Fig. 1; and the third, where the three bronze pennies are placed on the sole plate, either under the cylinder, Fig. 3, or the grate, Fig. 6. By this arrangement, the gas is fully supplied with air, while the chance of explosion is almost entirely obviated. When, however, the furnace is in operation at a white heat, if the gas supply-pipe is pinched, an explosion occurs, because, under the action of the hot furnace and the chimney, the air is immediately brought into excess. In such a case, as soon as an explosion is heard, the gas should be turned off, the chimney be moved aside, and the opening in the dome of the furnace be closed by a crucible cover. The draught of air is thus stopped. If now the gas is turned on fully, it takes fire properly in the body of the furnace, and, the chimney being replaced, the operation proceeds as usual.

The second point to be noticed is the form of the flue in the furnace roof, or dome, Fig. 5. By this contrivance, the rising current of flame and gas is bent twice at a right angle, and an obstruction is produced between the body of the furnace and the chimney, without which the gases would escape too readily into the chimney, and

burn there instead of in the furnace. If the roof, Fig. 5, is replaced by a flat perforated plate similar to Fig. 9—the same furnace and chimney being used—the diminution of heating power is very considerable.

The progress of an ignition is judged of chiefly by the colour of the fire, as seen through the crevices of the furnace between the pieces *f* and *g*, and *g* and *h*, in Fig. 1. The eye soon learns to distinguish the colour, which indicates an iron-melting heat.

The proper admixture of gas and air is judged of from the colour and quantity of flame which passes up the chimney. To enable the operator to see this flame, three small holes are bored in the chimney. The flame is never seen at the upper hole, unless the supply of gas is too large; but it is always visible at both the lower holes. As there are no valves to regulate the supply of air, due attention must be paid to the supply of gas.

MISCELLANEOUS.

Chair of Chemistry at St. Bartholomew's.—We learn that Mr. J. Alfred Wanklyn, Dr. Russell, F.R.S., Dr. Dupré, and Mr. Maxwell Simpson are spoken of as candidates for the above vacant chair.

The Chemical Society.—The first meeting of the session will be held on Thursday, November 3rd, at 8 o'clock, when Mr. A. H. Elliott will read a paper on "The Analysis of Cast-Iron."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 14, 1870.

From the report of the latest meetings of this Society, we learn that Mr. Roberts, chemist to the Royal Mint, London, has been elected a Member of the Society. This number contains the following original papers and memoirs:—

Action of Sulphuric Acid on Organic Chlorides which contain Nitrogen.—A. Oppenheim.—The author states that, after having previously studied the action of sulphuric acid on organic chlorides, he proceeded to the investigation of the action of that acid upon chlorides which also contain oxygen. He found that, generally speaking, there is no difference in this action; because, according to the degree of saturation of the substance, it either combines directly with H_2SO_4 , or Cl is driven off in the form of HCl , and, in its stead, H_2SO_4 combines with the substance. The molecule, HSO_4 , is readily replaced by hydroxyl. As an instance, the author quotes the monochlorohydrate of glycol, $C_2H_4O.HCl$, which behaves exactly as chloroethyl, C_2H_5Cl , there being formed, while HCl is given off, the conjugate acid, $C_2H_4O.H.SO_4H$. The lengthy paper contains, further, the account of a series of experiments made with benzoyl-chloride, which, when acted upon by sulphuric acid, yields a monobasic sulphobenzoyl acid, $C_6H_5.CO.SO_4H$. Acetyl-chloride, and the chlorides of phthalic acid, are acted upon in the same manner by sulphuric acid.

Sulphobenzoyl Acid.—E. Ador and A. Oppenheim.—This paper contains a detailed account of a comparative investigation instituted with the sulphobenzoyl acid mentioned in the foregoing paper, and with the same acid as obtained when prepared by a different method. The result is, that the identity of these bodies is fully established.

Nitro-Naphthol Acid.—O. Küchenmeister.—After referring to the researches made on this subject by MM. Schäffer, Wichelhaus, Merz, Mühlhauser, and others on this subject, the author treats, at great length, on α and β naphthol acid, both of which are readily nitrated. The α nitro-naphthol acid fuses at 194° , the β acid at 228° .

Products of the Distillation of Coal-Tar which have a High Boiling-Point.—C. Gräbe and C. Liebermann.—This memoir treats on pyren, $C_{16}H_{10}$, a body not to be confounded with the pyren of Laurent,

who, undoubtedly, had not obtained a pure substance, but a mixture of several hydrocarbons. The pyren here alluded to is a solid body, perfectly colourless when chemically pure; difficultly soluble in alcohol when cold, more readily so when boiling, and best soluble in benzol, ether, and sulphide of carbon; fuses at 142° . Pyren is characterised by combining directly with picric acid when solutions of these bodies are mixed together; this compound, $C_{16}H_{10} + C_6H_3(NO_2)_3OH$, crystallises in long needle-shaped red-coloured crystals. The memoir further gives an account of the substitution-products of pyren; nitro-pyren, $C_{16}H_9(NO_2)$; pyren-chinon, $C_{16}H_8(O)_2$; dibrom-pyren-bromide; tribrom-pyren, $C_{16}H_7Br_3$; and on the constitution of pyren expressed by a lengthy and very picturesque formula.

On Phenyl-Ether and Diphenyl-Oxide.—W. Hoffmeister.—Phenyl-ether is a solid, colourless body, having an agreeable aromatic smell; fuses at 28° ; boils at 248° ; is insoluble in water, but readily soluble in alcohol and ether. When this ether is acted upon by strong sulphuric acid, heat being applied, the result is the formation of phenyl-oxide bisulpho acid. The baryta salt of this acid—

is readily soluble in water, but not in alcohol and ether. Diphenyl-oxide.—This body was prepared by the author, and its properties investigated with the view to compare his results with those obtained by M. Lesimple (see *Ann. der Chem. und Pharm.*, vol. cxxviii, p. 375). The author confirms the correctness of the researches published in the periodical just quoted, and states that the formula of diphenyl-oxide is $C_{12}H_{10}O$.

Quadri-Phenylised Ethylen, a Derivative from Benzo-Phenon.—Arno Behr.—The author describes the preparation of benzo-phenon from benzoate of lime; and also the conversion of the benzo-phenon into a chloride of that substance, by heating it along with pentachloride of phosphorus to 180° , in a sealed tube for about eighteen hours' time. This chloride yields, when decomposed by finely-divided metallic silver, a new body, the quadri-phenylised ethylen, $C_{20}H_{20}$.

Dibrom-Benzol.—V. Meyer.—This paper contains a discussion on the position of the atoms of bromine in crystallised dibrom-benzol.

Miscellaneous Researches made in the Laboratory of Berlin University.—Dr. A. W. Hofmann.—This memoir is divided into the following sections:—On some derivatives of the isobutylic alcohol; isobutyl-benzol and isobutyl-anisol; action of bromine on the aldehyde of the ethyl series; contribution to the history of trichloro-acetic acid and trichloro-crotonic acid; action of cyanic acid on acrolein; action of chlorine upon hydrocyanic acid in alcoholic solution. The subjects herein alluded to are the results of the labours of several students who attend Dr. Hofmann's classes.

Miscellaneous Researches.—Dr. A. W. Hofmann.—This series contains the following subject-matter:—Aldehyde green.—The formula of this substance is $C_{20}H_{12}N_4S_2O$; it may be considered as formed by the union of 1 molecule of rosaniline, 1 of aldehyde, and 2 of sulphuretted hydrogen, which, by the action of aldehyde upon rosaniline in the presence of hyposulphite of sodium, may probably be according to—

(The eminent author desires it to be stated that he does not consider this formula as expressing the true composition of the aldehyde green, but merely an approximative expression; his researches on this subject are not yet complete.) Contribution to the history of the ethylen bases. Action of cyanogen on aniline. Action of cyanogen upon triphenylguanidine. New series of cyanic acid ethers. New method of formation of isonitrile. Diagnosis of primary, secondary, and tertiary amines. Delicate test for chloroform.—This test is based upon the fact that, when chloroform is mixed with aniline and an alcoholic solution of caustic soda, a very strong reaction takes place, and isonitrile is generated, which is readily recognised by its peculiar characteristic smell; this reaction is so delicate that, when 1 part of chloroform is mixed with from 5000 to 6000 parts of alcohol, the first-named substance is readily detected. Reagent for cyanuric acid when present in diluted solutions and in very small quantity.—This test is based upon the very difficult solubility of the sodium cyanurate in a hot and concentrated soda solution. Action of acetic acid upon phenyl oil of mustard (*phenyl senföhl*).

Contribution to our Knowledge on Phenyl-Xantho-Genamide.—Dr. A. W. Hofmann.

Separation of the Ethyl Bases from each other by means of Oxalic Ether.—Dr. A. W. Hofmann.—These memoirs, and most of the preceding papers of this eminent author, are too lengthy to admit of any useful abstraction.

Isobutyl-Benzol and Isobutyl-Anisol.—J. Riess.—This memoir treats on the constitution of isobutyl-benzol—

on para- and orthonitro-isobutyl-anisol; and on the question, how the group NO_2 is placed in some of these nitro-substitution compounds.

Contribution to the History of Trichloro-Acetic Acid and Trichloro-Crotonic Acid.—W. E. Judson.—This exceedingly lengthy monograph is divided into the following sections:—Trichloro-acetamide; trichloro-acetolide; trichloro-acetic acid isobutyl-ether; trichloro-crotonic acid; trichloro-crotonic acid ethyl-ether; chloride of trichloro-crotonic acid; trichloro-crotonamide; decomposition compounds of trichloro-crotonic acid; action of pentachloride of phosphorus on croton-chloral.

Products of the Action of Chlorine upon Aldehyde.—G. Krämer.—This paper contains a lengthy discussion and refutation of observations made by M. Wurtz on the author's labours on this subject, as published some time ago.

Methods of Water Analysis.—A. Müller.—Second paper on this subject, treating of the estimation of sulphuric acid and chlorine.

Amido-Toluylen-Sulpho Acids.—H. L. Buff.

Molecular Heat of the Hydrates of Sulphuric Acid, and on the Heat of Combination Evolved by their Admixture with Water.—L. Pfaunder.—A series of figures arranged in tabulated form.

Uratonil.—Dr. Krejci.—The subject referred to is the name given to a new mineral first found near Sedlec, Bohemia, but lately also near Welsendorf, Bavaria. This mineral does not fuse when heated in the blowpipe flame; it consists, in 100 parts, of—Water, 12.666; silica, 13.781; phosphoric acid, 0.448; sesquioxide of uranium, 66.752; alumina and peroxide of iron, 0.511; lime, 5.273. Formula—

Cotton Dressing.—O. Meister.—The author, residing at Zürich, Switzerland, states that a parcel of white calico, of English manufacture, was found, on analysis, to be dressed to the extent of over 25 per cent of the weight of the fibre, while 5 per cent of this dressing consisted of mineral matter. The calico was sold at a price below the value of the yarn it was made of.

Adulterated Starch.—O. Meister.—A sample of starch sent (not, however, from England, but from Germany) to a dresser of calicoes, &c., at Zürich was found to be adulterated with 16 per cent of gypsum.

Establishment of a Chemical Society at Zürich.—The last-named author communicates that (now some months ago) the company hitherto existing under the title of Chemical Harmonica has been converted into a regularly-established chemical society, under the presidency of Dr. Wislicenus. The papers read at this Society and the communications made will be published in the above-named periodical until further notice. The Society lost, a few weeks after having been inaugurated, one of its foremost members, by the death of Dr. A. P. Bolley, whose biography forms the concluding pages of this number.

Polytechnisches Journal von Dingler, second number for September, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Detection of Arsenic in Sulphuric and Hydrochloric Acids, in Subnitrate of Bismuth, and in Antimonio-Tartrate of Potassa.—Dr. A. Bethendorf.—Take a thoroughly clean and dry test-tube, of not too narrow a bore; put into it as much pure protochloride of tin as can be placed on the point of a knife; next add from 4 to 6 c.c. of pure hydrochloric acid (containing 25 per cent of real acid, sp. gr. about 1.12); add, after this, gradually, from 2 to 3 c.c. of the sulphuric acid to be tested, taking care to move the test-tube very gently. If a white precipitate ensues, the addition of a few drops of the hydrochloric acid will be required to restore the liquid to perfect limpidity. If no arsenic is present, the liquid remains clear and colourless, even after standing for a time; but, if even a trace of arsenic is present, the fluid becomes at first yellowish, next brownish coloured, and at last the metallic arsenic is deposited as a deep greyish brown flocculent substance. Even with only 1-500,000th part of arsenious acid a colouration ensues. It is essential that, when the sulphuric acid is added, the liquid should become hot; if, therefore, that acid is too dilute to cause heating, the test-tube and contents should be warmed over a spirit flame. The testing of hydrochloric acid only differs in this particular: that, instead of taking, as above stated, pure hydrochloric acid, the acid to be tested is taken, and pure concentrated sulphuric acid is applied. The testing of the subnitrate of bismuth is carried out in the following manner:—About $\frac{1}{2}$ a gram. of the subnitrate is placed in a test-tube; a quantity of 1 c.c. of pure and concentrated sulphuric acid is next added, to expel the nitric acid. After this has been driven off, the tube being kept in a vertical position, from 4 to 5 c.c. of pure hydrochloric acid are added; when the liquid has become quite clear, about 1.5 to 2 grms. of pure protochloride of tin are added; after this salt has been dissolved, about 3 c.c. of strong and pure sulphuric acid are added; and, if the mixture does not then become very hot, it is heated just to the boiling-point. The colouration and precipitation of arsenic above described take place after a shorter or longer time, according to the quantity of that substance which is present; but it ought, of course, to be absent. The testing of tartar emetic is effected in the following manner:—As much tartar emetic as can be carried on the point of a large-sized knife, and twice as much protochloride of tin, are placed in a wide test-tube; 4 to 5 c.c. of the pure hydrochloric acid above alluded to are added; and, next, 2 to 3 c.c. of pure concentrated sulphuric acid. If required, the mixture is heated. Neither the oxides of bismuth nor antimony are reduced to the metallic state by this reaction.

Solubility of Sulphur in an Aqueous Solution of Carbonate of Soda and in Linseed Oil.—Dr. J. J. Pohl.—The author experimented with flowers of sulphur, previously well washed and dried at 100° , and with an aqueous solution of pure anhydrous carbonate of soda containing 5.6 per cent of salt. Sulphur was found to be insoluble in that solution at 25° ; but, when the sulphur was digested with the aforesaid solution, heated to 100° for a period of ten hours, it was found, on testing the soda solution, that the quantity of sulphate of baryta obtained corresponded, on an average, to a quantity of 0.0676 per cent of sulphur dissolved. The solubility of sulphur in linseed oil increases with the increase of temperature—at 25° , linseed oil dissolves 0.63 per cent of sulphur; at 65° , 2.587; at 130° , 4.935; and at 160° , 9.129 per cent. Linseed oil which has taken up that quantity of sulphur keeps dissolved,

even after having been standing for a fortnight at 20°, 6·9 per cent; and even after ten weeks' time, no more sulphur is deposited than occurs at first.

Occurrence of Raw Sugar which contains Dextrine, and on the Detection and Estimation of that Substance.—Dr. C. Schiebler.—The author states, in this lengthy paper, chiefly the following facts:—That now and then raw beet root sugar contains dextrine; that alcohol is not an absolute test for the presence of this substance, while iodine in dilute solution is a better test. In order to test for the presence of dextrine in raw sugar, the author proceeds as follows:—13 grms. of the sugar in question are dissolved in 50 c.c. of water. This solution is filtered, and a portion thereof is mixed with about four times its bulk of alcohol at 95 per cent, which, if dextrine is present, produces a milky cloudiness in the fluid. Another portion of the liquid is treated with a solution of iodine, consisting of 0·1 gm. of iodine and 1·5 grms. of iodide of potassium, dissolved in a little water, and next diluted to 100 c.c. This solution, which is of a sherry colour, produces the characteristic colouration (purplish red) if dextrine be present; but, if the sugar solution is alkaline, the first drops of the iodine solution do not produce a colouration at once. The quantitative estimation of the dextrine can only be effected by analysing the sugar, after having been treated with dilute sulphuric acid, and next applying the well-known copper liquid test.

Addition of Poisonous Substances to Bread.—Dr. H. Eulen-berg and Dr. H. Vohl.—This paper, too lengthy for any useful abstraction, treats on the adulteration of bread by the addition thereto of sulphate of alumina, alum, and the sulphates of copper and zinc, and on the methods of testing for the presence of these substances in bread.

Application of Tungstate of Soda to form an Elastic Mass.—Dr. Sonnenschein.—When glue, in thick solution, is mixed with tungstate of soda, and hydrochloric acid is added, there is thrown down a compound of tungstic acid and glue, which, at from 30° to 40°, is so elastic as to admit of being drawn out into very thin sheets. On cooling, this mass becomes solid and brittle; but, on being heated, it becomes again soft and plastic. This material has been successfully employed, instead of albumen, in calico-printing, in order to fix the aniline colours upon cotton; the further applications of this substance are in tannin, but the resulting leather becomes as hard and stiff as a plank of wood. The preparation is recommended as a lute or cement.

Journal für Praktische Chemie, No. 15, 1870.

The following original papers and memoirs are contained in this number:—

Relation between the Crystalline Shape and the Chemical Constitution of some Organic Compounds.—Dr. P. Groth.—The continuation and end of this lengthy essay.

Lithiophorite, a Manganese Ore containing Lithia.—A. Frenzel.—The mineral here alluded to was first found, some years ago, in the neighbourhood of Schneeberg (Saxony), and considered as being psilomelan. The author, however, having investigated this substance, gives the following facts about it:—Sp. gr., 3·14 to 3·36; hardness, slightly above that of calcareous spar; colour, bluish black; amorphous; gives off water when heated in a test-tube, and evolves chlorine when heated in the presence of hydrochloric acid; does not fuse when heated before the blowpipe, but imparts to the flame an intensely carmine-red colour; fused along with borax or microcosmic salt, it yields the characteristic tests for manganese. A full analysis of this mineral will be published afterwards; the author now only gives the following particulars:—Lithia, 1·15 per cent; alumina, 15·42 per cent. This mineral is, says the author, a product of decomposition, but, for all that, a new and specific mineral.

Isotomorphism of Oxide of Tin and of Titanic Acid, and on the Crystalline Form of Zirconia.—G. Wunder.—A crystallographical essay.

Chemical Constitution of the Phosphorus-Platinum Compounds described by MM. A. Cahours and A. Gal in Comptes Rendus (vol. lxx., pp. 897, &c.).—Dr. H. Kolbe.

Isotaurine.—M. Kind.—This paper, a preliminary notice, contains the announcement that the author has discovered a new body, which, on being analysed, led to the following formula:— $C_{12}H_{14}H_2N_2SO_4OH$. He has named it isotaurine, and promises further particulars.

Amido-Sulpho-Phenol.—L. Glutz and L. Schrank.—This paper is also a preliminary notice. The authors describe, at some considerable length, the methods by which they have obtained, from the sulphonic acid of the nitrophenyl-sulphuric acid, several other compounds, among these, nitrophenyl-sulphuric acid chloride (*nitrophenyl-schwefelsäurechlorid*), $(C_6H_4NO_2)SO_2Cl$, a crystalline body, insoluble in water, soluble in ether, and also in boiling alcohol, although it becomes partly decomposed thereby, and fuses below 100°. By acting on this body with metallic tin, the authors have obtained the hydrochloride of the amido-sulpho-phenol, $(C_6H_4NH_2)SH.HCl$.

Bromonitro-Benzol-Sulpho Acid and some of its Derivatives.—F. G. Fricke.—This paper, again styled preliminary notice, contains the following sections:—Action of ammonia upon bromonitro-benzol-sulpho acid; action of potassa upon bromonitro-benzol-sulpho acid; action of aniline upon bromonitro-benzol-sulpho acid.

Water of Crystallisation.—F. von Kobell.—A lengthy monograph on this subject.

Influence which Temperature Exerts on the Molecular Power of some Substances Endowed with the Property of Circular Polarisation.—Dr. C. Tuchschnid.—This very lengthy essay is illustrated with engravings and a series of tables containing a large number of figures.

Pharmaceutische Zeitschrift für Russland, No. 4, 1870.

This number contains the following original papers and memoirs:—

Some Narcotics Used by the Inhabitants of Central Asia.—Dr. Palm.—This paper contains a brief notice on *Buhsa*, a fluid which appears to possess highly intoxicating power; so much even, that, according to the author's statement, the Russian military authorities have been obliged to forbid the preparation of this beverage, which, being in great favour with the troops, and preferred to other spirituous fluids, renders the men unfit for duty in a very short time. *Buhsa* is prepared by the Kirghisen in the following manner:—Millet is rubbed to a pulp with water; and, after having been diluted with more water, and occasionally with mare's milk (this milk is largely used by the inhabitants of Central Asia), the mixture is poured into large stoneware jars, which are tightly corked, and afterwards buried in the soil. The vessels containing the liquid are left imbedded therein for about ten days; and, after having been dug up, the fluid is transferred to glass wine-bottles, which, after having been well corked, are left standing for a few days, and then offered for sale at the rate of from 3 to 5 kopeïks each (6d. to 10d.). The liquid thus prepared exhibits a greyish colour (somewhat akin to thin barley-water), and is turbid, there being a thick sediment in the bottles. On being uncorked, supposing the liquid to be matured, the beverage escapes in a very brisk manner, owing to the large quantity of carbonic acid present. The taste of this fluid is tart and spirituous; but the after-taste is very unpleasant, owing to the presence of fusel oils. Although the ingredients from which this drink (millet beer) is prepared are somewhat innocent, the effects of the imbibing of this fluid upon the system are not by any means mild; these the author refers to the presence of the alcohols of the higher fatty acids, in addition to alcohol, aldehyde, acetic, lactic, valeric, and traces of fatty acids and their alcohols (viz., fusel oils). Notwithstanding the Russian Government takes all possible measures to prevent the preparation and sale of *buhsa*, it is a popular drink; and, moreover, its mode of preparation from millet yields a substitute for yeast for baking purposes, and the prepared *buhsa* is largely applied for that purpose. The author next treats on three kinds of opium. That locally known as Bucharic opium is not the product of Central Asia, but imported overland from Hindostan; the two other kinds (viz., Chinese and Samarkand drugs) were found of good quality. The *Haschisch*, or *Chaschisch*, from *Cannabis indica*, is next alluded to; it is used in various forms, and by the Mahomedan women, in the shape of lozenges, known as *goikant*, which literally means yellow sugar, but consisting of sugar, haschisch, cinnamon, ginger, pepper, cloves, and gum.

Analysis of a Crude Potash.—Dr. Palm.—At a distance of 80 wersts from Taschkent (the werst is a Russian measure, equal to 1066·78 metres; 104·1555 wersts are equal to 1 degree of the meridian) the Kirghise prepare, from various wild plants, a kind of potash which occurs in the trade (in Central Asia) as a hard kelp-like substance, very difficultly soluble in boiling water, and leaving a carbonaceous residue. The author found this substance to contain, in 100 parts:—Carbonaceous matter, 5; soda, combined with carbonic acid, 36·8; chloride of sodium, 7·3; lime, 5·5; potassa, 3·85; magnesia, 1·4; alumina, 0·64; carbonic acid, 26·12; chlorine, 11·26; sulphuric acid, 1·84; silica, 0·05; iron and manganese, traces. The author calls attention to the fact that the large percentage of soda in this material is due to the very generally prevailing impregnation of the soil of the steppes, for thousands of wersts in extent, with carbonate of soda and chloride of sodium. The shrubs and plants which serve to prepare this article are such as can only grow in a similar soil.

Preliminary Notice on the Milky Juice of an Euphorbiaceous Plant.—Dr. Palm.—After referring to some strictly botanical particulars concerning a plant found in the neighbourhood of Taschkent, the author states that the milky juice which this vegetable yields while being cut is at first perfectly homogeneous; but, in a few minutes, more than three-fourths of the bulk of this fluid becomes coagulated—that is to say, the caoutchouc which is nearly always present, in greater or less quantity, in all milky vegetable juices separates, leaving a fluid which exhibits, simultaneously, an ammoniacal and ethereal odour. The caoutchouc, once separated from its menstruum, cannot be united with it any more. The taste of this milky juice is at first mild and oily, but soon leaves an acrid, sharp, burning taste, which even brings on inflammation of the throat. Our readers are reminded that all euphorbiaceous plants are more or less poisonous, while some among them yield the most virulent acid vegetable poisons we are acquainted with.

No. 5.

This number contains the following original papers and memoirs:—

The Manner in which the Nitrogen is Distributed in the Different Parts of the Black and White Henbane (*Hyoscyamus Niger et Albus*) during the various stages of the Development of these Plants.—E. Thorey.—This lengthy monograph contains the results of a long series of experiments made with the above-named plants, as a whole, and their different parts—viz., roots, leaves, stems, seeds—and at various periods of their growth, with the view to ascertain the partition of the various nitrogenised constituents of these plants at various epochs of their life. The essay is too lengthy, and too much filled with a series of results exhibited in tabulated form, to admit of any useful abstraction, notwithstanding the great value of this labour in a photo-physiological point of view, as well as in its practical bearing of the applications made of *hyoscyamus* in medicine.

No. 6.

This number opens with and contains no other original paper than—

Treatise on the Various Analytical Methods in Use for the Determination of the Quantity of Tannic Acid present in Catechu, Ratanhia, Kino, and other Drugs.—Dr. Günther.—This exhaustive monograph, the first portion of which is found in this number, and is continued in Nos. 7 and 8, contains a review of all the various methods which have been proposed for the estimation and quantitative determination of the tannic acid present in the commercial substances above referred to, and chiefly applied in dyeing, calico printing, and tanning. The author not only describes the various methods, but has tested the value of each method practically and with great care. Among the results arrived at, and the conclusions drawn from his researches, we quote the following as the most important:—None of the different methods which have been applied for the quantitative estimation of tannic acid answers the purpose completely—that is to say, that a method which yields excellent results with nutgalls is not equally suitable for sumack, catechu, and other similar substances; for the reason that these materials contain either other substances along with tannic acid or specific modifications of the same. We regret that the very great length of this monograph prevents us entering into further details on this subject.

Nos. 7 and 8.

*These numbers contain no other original papers than that quoted under No. 6.

No. 9.

This number contains the following original papers and memoirs:—

Contribution to our Knowledge of the Aconite Alkaloids.—Dr. F. A. Pluckiger.—This paper treats on the alkaloids contained in several plants known by different botanical names, but all belonging to the species *aconite*. The author distinguishes between aconitine, pseudoaconitine, napelline, and lycoctonine. The first of these alkaloids is the most important, and possesses, among others, the following properties:—It becomes soft and pasty in boiling-water, and imparts to phosphoric acid, when evaporated along with that substance to a syrupy consistence on a water-bath, a violet colour, which remains even for days after the cooling of the mass. The aqueous solution of aconitine has a bitter taste, but not acrid; the solution is not precipitated by chloride of platinum, but the solution of the double salt of iodide of potassium and iodide of mercury produces, in such solutions, a copious non-crystalline precipitate. Aconitine is very soluble in ether, chloroform, and alcohol; it is anhydrous; its nitrate crystallises readily. Pseudoaconitine does not become pasty in hot water, and does not exhibit the reaction with phosphoric acid above alluded to; it is very difficultly soluble in water, ether, alcohol, and chloroform; and crystallises better (in large prismatic-shaped crystals) than aconitine.

NOTES AND QUERIES.

Tabachere.—Can any of your readers give me information as to the chemical composition and properties of this substance. It is said to be produced from the bamboo.—WM. LANT CARPENTER.

Anthracene.—(Reply to "H. J.")—The large manufacturing firm of Messrs. Gehe and Co., at Dresden, forward us their price lists, published quarterly; in their list for September, the price of anthracene is quoted at 2 Rths. per pound, equal to about 6s. 6d. English currency.

Ethers in Wine.—Can any of the readers of "Notes and Queries" inform me where I shall find Berthelot's formula for calculating the amount of the compound ethers contained in wine, and also the method pursued for the estimation of those ethers?—H. T. B.

Hydrogen Apparatus.—T. A. White wants to know how to use a "hydrogen apparatus," said to be Woolfe's, having a cylinder for generating hydrogen, with a blowpipe attached to it underneath, in a drawer, in the front of which is a small spirit-lamp to ignite the hydrogen jet.

Black Japan.—(Reply to "S. R. H.")—We have not space to enter into particulars on this subject; you are referred to the "New York Coach-Makers' Monthly Magazine," and to Cooley's "Cyclopaedia of Practical Receipts," both of which works may be inspected at the Library of the Commissioners of Patents.

Estimating Cyanides.—(Reply to E. Outhet.)—Since cyanides are very readily decomposed by acids, and since the substances employed to make the brown sulphate of ammonia are saturated with acid previous to evaporation, it is hardly likely that any cyanide should be left undecomposed in the crude sulphate of ammonia; but, should there be any left, you will be enabled to estimate it by the methods fully described in the fifth edition of Dr. Fresenius's "Quantitative Chemical Analysis," edited by A. Vacher, page 170 and following.

TO CORRESPONDENTS.

E. Kernan.—There is an English edition published in America. C. E. Craven.—(1) The work will not be ready for some time to come. (2) We do not know of such a work in English.

Querist.—Mr. Wanklyn is not a foreigner. On referring to Poggenorff's "Biographical Dictionary," we find that he was born at Ashton-under-Lyne, near Manchester. Last year he was elected a Corresponding Member of the Munich Academy of Sciences.

Vox.—(1) The Royal School of Mines is in Jermyn Street, W. (2) Dr. Yeats's book, reviewed in No. 568 of our journal, is the only work we know of treating on the subject.

B. W. Gibbons.—Received.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7, IRWILL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL AND TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Caesar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Polytechnic Institution, Regent Street.

—EVENING SCIENCE INSTRUCTION.—Classes meet on the following Evenings:—Chemistry, on Tuesdays; Practical Chemistry, on Tuesdays; Electricity and Magnetism, on Thursdays; Acoustics, Light, and Heat, on Thursdays; Animal Physiology, on Fridays; Metallurgy, on Fridays. For Prospectuses apply to the Secretary, Mr. J. Cousins, at the Institution.

Royal Polytechnic.—The Praeger Family

give their Refined CONCERTS daily at half past 3 and 8.—Professor Pepper exhibits daily, at Quarter to 3 and quarter-past 7, the effects and describes the various modes of causing GHOSTS of human beings to appear and disappear, crawl, leap, and dance on walls, or float in space; also shows the latest novelty, viz., Grotesque Shadow Faces produced on the screen by Walnut Kernels.—Notes from a popular Opera by Suchet Champion.—The whole is.

VOL. XXII. No. 571.

ON THE SOLVENT POWER OF ANHYDROUS LIQUID AMMONIA.*

By Professor CHARLES A. SEELY, of New York.

PROFESSOR SEELY states that he has made the discovery that ammonia has a solvent power upon certain metals, and that he has actually succeeded in obtaining a solution of sodium in liquid ammonia. This solution presents all the physical characteristics of a true solution. On evaporation, the sodium is gradually restored to the metallic state in the same continuous manner in which the solution has been affected. The colour of the solution is a very intense blue, and its opacity or high tinctorial power is urged as an argument in favour of the notion that the metal is in simple solution. Weyl had made the capital discovery that when gaseous ammonia is condensed by pressure and cold on sodium, a blue liquid is the product, but he had mistaken the nature of this product. Professor Seely has experimented on various substances, and has concluded that ammonia is a solvent of metals; that other metals can be dissolved in ammonia, and the details of his experiments in confirmation of the views, will be the subject of another paper.

ON EDIBLE EARTH.†

By Prof. C. W. C. FUCHS.

To the list of the earth-eating people the Javanese must be reckoned; a fact brought to our knowledge by Alex. von Humboldt. From the specimens which I have had the opportunity of seeing, it is to be inferred that earths of very different external appearance and of different character are eaten. One deposit of such edible earth, possessing an intensely red colour, exists in the neighbourhood of Sura Baja, between strata referable to the time of the latest tertiary.

This earth is formed into thin cakes, having a diameter of from 1—1½ inches; it is then dried over an open fire, and in this condition is brought into the market. It is perfectly smooth to the touch, and is composed of materials in the finest state of subdivision. By a chemical analysis, to which I subjected it, after removing the thin stratum of soot, which settles upon it during the process of drying over the fire, I convinced myself that it does not contain the slightest trace of an organic substance. The analysis gave the following result:—

SiO ₂		50.63
AlO ₃		21.32
FeO ₃		10.47
H ₂ O		12.97
CaO		2.40
MgO		0.33
K ₂ O		1.02
Na ₂ O		0.23

99.37

Of the water, 6.36 per cent was driven off below red heat. The remaining 6.61 per cent disappeared only when the test portion was heated to bright redness. From the analysis it is apparent that the earth consists of a clay

* Abstract of a paper read before the American Association for the Advancement of Science, 1870.

† Communicated by Dr. W. H. Wahl. From advance-sheets of the *Journal of the Franklin Institute*.

rich in iron, in which is still retained small quantities yet undecomposed, of the minerals from which it derived its origin. In this way the trifling percentage of potassa and soda may be accounted for. Taking away the accessory alkalies, and so much of the silica as they demand, there remains behind a clay of the formula:—

Humboldt suggested that the probable explanation of the earth-eating habit might be found in the desire to fill the stomach, and thus, in a measure, to allay the pangs of hunger. This view of the subject may be satisfactory when applied to those rude people who devour it in great quantity; but it will not apply to the case of the Javanese, who make this use of but trifling quantities. With these it is much more probable that the physical properties of the earth alone are sufficient to furnish the cause we are seeking.

Upon rubbing it, not the slightest grittiness is perceptible, and on being moistened with water it forms a smooth and unctuous mass. The enjoyment derived from eating it seems to reside in the similarity of the sensations it produces with those derived from the eating of fatty substances. In many parts of Würtemberg the quarrymen have the habit of eating the smooth, unctuous clay which collects in the fissures of the rocks. The term "Mondschnalz," which they apply to it, would seem to refer to the enjoyment they experience in the process of eating.

ON THE CALORIFIC POWER OF HARE'S BLOWPIPE.

By W. MARSHALL WATTS, D.Sc.

THE explanation of the formula for the calculation of the temperature of the oxy-hydrogen flame, asked for by Professor Wurtz, is easy. In the combination of 1 lb. hydrogen with 8 lbs. oxygen 34,462 units of heat are produced, that is, enough heat to raise 34,462 lbs. water from 0° C. to 1° C. This heat is expended first in raising the temperature of the water produced from 0° C. to 100° C., then in converting it into steam at 100° C., and finally in raising the temperature of the steam from 100° C. to the temperature of the flame. Calling this unknown temperature t we have the equation—

$$34462 = 9 \left\{ 100 + 537 + (t - 100) 0.4805 \right\} \\ \text{whence } t = \frac{34462 - 9(637 - 48.05)}{4.3245} \\ = 6743^\circ$$

Or we may suppose the water produced first of all changed into steam at 0° C. in which case we must take the latent heat equal to 606.5, and in this case—

$$34462 = 9(606.5 + t \times 0.4805) \\ \text{whence } t = 6707^\circ.$$

NOTES ON THE EXTINCTION AND REDUCING POWER OF MERCURY.*

By Dr. ISIDOR WALZ.

At the last meeting of the chemical section of the Lyceum I drew attention to the conversion of liquid zinc-amalgam to a gray powder, when shaken with a solution of potassium bichromate. Subsequently I became convinced that this phenomenon was solely due to the extinction of the mercury, and have made a number of experiments regarding the phenomenon, of which I present the following results. It is hardly necessary to state that the mercury used was absolutely

* Read before the New York Lyceum of Natural History.

pure. It is very difficult, but essential, to use chemically pure mercury, as even a very small trace of a foreign metal is often sufficient to influence the results materially. The experiments were made in ordinary test-tubes, in which the materials were shaken a length of time varying from a few seconds to 10 minutes. I believe that we ought to distinguish between two methods or kinds of extinction, namely the mechanical and the chemical. The former is effected by a very large number of solutions of neutral salts, which exert no chemical action on mercury, and even by pure water, if shaken long enough. The extinction of the mercury in this case is produced simply by the interposition of fine films of the liquid between the globules, into which the mercury is separated by the mechanical agitation, and which are thus prevented from running together again. By mechanical extinction, mercury is converted into what appears to be a fine powder, which, however, never loses its white colour and metallic appearance, and under the lens its globular structure is clearly seen.

Quite interesting in many cases are the reactions which accompany the chemical extinction of mercury, which takes place when the metal is shaken with a solution of a salt, by which it is chemically affected. In these cases, the newly-formed mercury compounds act in the same way as the films of liquid in the former instance, preventing the separate globules from re-uniting. A finer division of the metal is obtained in less time than by the mechanical method, and the resulting metallic powder is generally of a dull gray leaden colour. When a solution of potassium bichromate is poured upon mercury, the convexity of the surface is at once destroyed; presently the surface is tarnished and begins to look wrinkled, while, at the same time, a greenish-black powder commences to deposit itself. This greenish-black powder is a mixture of chromic and mercurous oxide; it is formed abundantly when the two liquids are agitated more or less strongly; the mercury is at the same time completely extinguished, and at the end of the reaction neutral potassium chromate alone remains in solution, which is not acted upon by mercury. Ferric chloride extinguishes mercury; ferrous and mercurous chlorides are formed. Potassium permanganate also acts upon the metal; manganic and mercurous oxides are deposited, while potassic hydrate remains in solution. Mercury shaken with Fehling's solution is simply extinguished mechanically, when all the reagents used are pure; but when a very small quantity of zinc-amalgam is added, Cu_2O is reduced from the solution.

A solution of potassium ferricyanide does not affect the fluidity of mercury; but when the two are shaken together, a green powder is formed in large quantities, which, if allowed to stand, changes to a dark, and later still to a light, blue colour. Potassium ferrocyanide appears to be formed at the same time. I am still engaged in studying this interesting reaction, and will endeavour to determine if this blue powder is Prussian blue or not. Sodium hyposulphite, also, does not affect the mercury physically; on agitation, however, a heavy black powder, mercuric sulphide, is formed. Its amount increases with the lapse of time, and in one of my test-tubes, which has hardly been disturbed for weeks, the original black sulphide has assumed a yellowish red colour.

I conclude from these observations that the reducing power of pure mercury is greater than is generally supposed, and I expect to be enabled to obtain some interesting results from an extension of these experiments.

I have repeated some of Loew's experiments, which he described at our last meeting, and can state that similar results are obtained by substituting palladium bichloride for the platinum salt. I cannot, however, yet coincide with him in considering his final product as hydrogenium-amalgam, as by every method by which it has yet been made it contains another metal besides mercury and hydrogen, namely, either platinum, palladium, gold, or silver, in no inconsiderable proportion.

SPECTROSCOPIC NOTES.

By Prof. C. A. YOUNG, Ph.D., of Dartmouth College.

Spectrum of a Solar Spot, April 9, 1870, P.M.

EXAMINED the spectrum of a large group of spots a little north and east of the sun's centre.

The nucleus of the most southerly member of the group reversed the C line finely, turning it into a conspicuous bright line for about 20" of its length, without any distortion, however, such as is common upon this (dark) line in the neighbourhood of spots.

F was also reversed, but rather faintly.

D_3 could not be made out at all in the nucleus spectrum; neither were 2796 (the numbers refer to Kirchhoff's map) nor h reversed. I thought, however, that they were somewhat thinned.

The reversal of C and F continued through the whole afternoon.

On the other hand, many of the dark lines were widened and deepened in this nucleus spectrum in the manner which the description and figures of Mr. Lockyer have made familiar. Many also were unaffected. Among these were notably a , B, E, 1474, the four lines of b , 1691 and G.

The two sodium lines D_1 and D_2 , and 850 (Fe) were distinctly, but not greatly, widened.

The effect was most marked upon the following:—864 (Ca), 877 (Fe?), 885 (Ca), 895 (Ca and Li), 1580 (Ti), 1599 (Ti), 1627 (Ca), and 1629 (Ti). I have marked 877 doubtful, because there lies very near it a line whose origin is

unknown, and I am not sure to which of the two the thickening was due. The Titanium lines are identified as such by reference to Angström's atlas. I was greatly surprised at the prominence they assume in the spot-spectrum, as they are inconspicuous in the normal spectrum; and a similar remark applies to the calcium lines.

I do not intend to convey the idea that the lines mentioned were the only ones that were much deepened; there were many others, mostly faint, affected to nearly the same degree, but I had not time to identify them.

There was, at the same time, an exceedingly brilliant protuberance on the south-west limb of the sun (position angle 230°), near, but not over, a large spot which was just passing off. At the base of this prominence, which was shaped like a double ostrich plume, the C line was intensely brilliant, so that the slit could be opened to its whole width in studying the form above described, but it was not, so far as I could see, in the least distorted. On the other hand, the F line, also very brilliant, was shattered all to pieces, so that at its base it was three or four times as wide as ordinary, and several portions of it were entirely detached from the rest. The figure, without pretending to exact accuracy, and for the sake of distinctness a little exaggerated, gives a fair idea of the nature and extent of the "shattering" alluded to.

Since the C line was not similarly affected, it is hardly possible to attribute this breaking up of F to cyclonic motions in the gas from which the light emanates, and it becomes very difficult to imagine a cause which can thus disturb a single line of the spectrum by itself. Possibly this appearance may be the result of local absorptions acting upon a line greatly widened by increase of pressure or temperature.

It continued unchanged for more than half an hour, and until the sun passed out of sight behind a building. The observations were made with the 5-prism spectro-scope.—*Journal of the Franklin Institute.*

NOTES OF CONTRIBUTIONS TO MINERALOGICAL CHEMISTRY.*

By Prof. A. H. CHURCH, M.A.

I AM anxious to draw the attention of the chemical section to the special features of certain mineralogical researches on which I have been engaged for the last six years. I have had three objects chiefly in view.

- (1.) The elucidation of obscure minerals by exact and minute analysis.
- (2.) The discovery of new species and varieties.
- (3.) The chemical structure of minerals.

Besides the direct determination of every ingredient of a mineral, I have been led to consider the mode of desiccation of a mineral as of the very highest importance to the attainment of satisfactory results. When I commenced, in 1864, one series of experiments, "the revision of the mineral phosphates," I wrote, "If chemists had invariably analysed natural phosphates in the same manner as the preparations of the laboratory, the discrepancy in the above results could scarcely have occurred. Many other hydrous minerals are in the same predicament—the hygrometric condition at the time of analysis has not been determined." In numerous instances I have been able to throw much light upon the constitution of a mineral, and also to explain the most singular anomalies and divergences in earlier analyses by simply drying the specimen previous to analysis, first over oil of vitriol *in vacuo*, then at 100°, and then at gradually increasing temperatures. I have drawn up in a compact form, and in alphabetical order, a brief account of some of the chief minerals, new, rare, anomalous, or obscure, which I have lately analysed. Many of the results have been already published, but several new analyses are included. The several series which are still being continued are—

Revision of the mineral phosphates.

Chemical researches on new and rare Cornish minerals. Mineralogical notices.

Atacamite.—New to Britain.

Bayldonite.—New to science.

Calaité.—Revision of formula.

Chalcophyllite.—Revision of formula.

Childrenite.—Revision of formula.

Chloropal.—New to Britain.

Churchite.—New to science.

Cornwallite.—Revision of formula.

Delvauxite.—Revision of formula.

Dufrenite.—Revision of formula.

Hisingerite.—New to Britain.

Limnate.—Analysis of a remarkably pure specimen.

Melanconite.—New form.

Namaqualite.—New to science.

Pagodite.—New analyses.

Restormelite.—New analyses.

Tallingite.—New to science.

Tasmanite.—New to science.

Tavistockite.—New to science.

Woodwardite.—New to science.

In addition to the minerals named above, experiments have been made upon several others, the results of the analyses having been published in some instances, in others being reserved till more conclusive. These minerals are:—

Autunite.
Brochantite.
Devilline.
Langite.
Ehlite.

Marmatite.
Phosphochalcite.
Prasine.
Torbernite.

Atacamite, $\text{CuCl}_2 \cdot 3\text{CuO} \cdot 4\text{H}_2\text{O}$; or $\text{CuCl}_2 \cdot 3\text{CuH}_2\text{O}_2 \cdot \text{aq}$.—This species is found in Wheal Cock, near Wheal Botallack, Cornwall. Until I identified specimens from that locality it does not appear to have been recognised as a British mineral. The experimental and theoretical percentages are here compared.

	Experiment.	Theory.
Cu	13.57	14.3
Cl	15.20	16.0
CuO	54.32	53.6
H ₂ O	16.91	16.2
	100.00	100.0

For details see *Journ. Chem. Soc.* (2), iii., pp. 81, 213; Dana's "Mineralogy," 5th ed., p. 121.

Bayldonite, $\text{PbCu}_{22}\text{AsO}_4 \cdot \text{CuH}_2\text{O}_2 \cdot \text{aq}$.—This lead and copper arsenate is a distinct species, first recognised in 1865. It is by no means a rare material, many specimens occurring in old collections of Cornish minerals under erroneous designations. It presents the appearance of minute mammillary concretions with a drusy surface: its density is 5.35, and its hardness 4.5; its analytical and theoretical percentages are as follows:—

	Experiment.	Theory.
PbO	30.13	30.7
CuO	30.88	32.8
As ₂ O ₅	31.76	31.6
H ₂ O	4.58	4.9
Loss	2.65	—
	100.00	100.0

For further details see *Journ. Chem. Soc.* (2), iii., p. 265; Dana's "Mineralogy," 5th ed., p. 565.

Calaité, $\text{AlPO}_4 \cdot \text{AlH}_3\text{O}_3 \cdot \text{aq}$.—The true Persian turquoise has been analysed with rather perplexing results. But if the intruding copper, iron, and manganese phosphates be excluded, the composition of the true basis of the turquoise is arrived at. The direct analytical results establishing the true formula of this species are here given.

	Experiment.	Theory.
P ₂ O ₅	32.86	32.6
Al ₂ O ₃	40.19	46.9
CuO	5.27	—
FeO	2.21	—
MnO	0.36	—
H ₂ O	19.34	20.5
	100.23	100.0

For further details see *CHEM. NEWS*, vol. x., p. 290.

Chalcophyllite.—

$\text{Cu}_2\text{H}_2\text{AsO}_4 \cdot 4\text{aq} \cdot 6\text{CuH}_2\text{O}_2 \cdot \text{Al}_2\text{H}_6\text{O}_6 \cdot 11\text{aq}$.—

Chalcophyllite, the tamarite of Brooke and Miller, has been often analysed with most contradictory results. By numerous trials I found that part of its water (11 aq. above) was held much less tenaciously than the rest, and that it invariably contained a definite amount of alumina. The foregoing revised formula represents the results of my analyses.

	Experiment.	Theory.
CuO	46.14	44.82
Al ₂ O ₃	5.97	7.26
As ₂ O ₅	15.54	16.21
H ₂ O	31.75	31.71

Further details in *Journ. Chem. Soc.* (2), viii., p. 168.

Childrenite.—As yet I am unable to speak with confidence as to the true constitution of childrenite: I have made many analyses of the mineral, but the samples picked for analysis, though selected fragment by fragment, under the microscope, contained, besides one per cent of

* Read before the British Association, Liverpool Meeting, Section B.

silica, evident traces of chalybite. I have, however, learnt that the only analysis of the mineral yet published is too low in the phosphorus pentoxide and too high in the ferrous oxide, that a part of the iron is in the ferric condition, and that the formula suggested by Rammelsberg will have to be modified.

Chloropal, $\text{Fe}_2\text{O}_3\cdot 3\text{SiO}_2\cdot 5\text{H}_2\text{O}$?—I first detected chloropal, in England, in 1865, in seams of granite in a quarry about three-quarters of a mile from the old tin mine of Carclaze, St. Austell; it has since been found in abundance in other parts of Cornwall. The state of oxidation of the iron varies; there is always some in the ferrous condition. The water is partly held in a state which the heat of the water-oven suffices to alter; the formula of this mineral thus dried is probably $\text{Fe}_2\text{O}_3\cdot 3\text{SiO}_2\cdot 3\text{aq}$. Some specimens contain a good deal of alumina (8·58 per cent in one instance) and traces of lime and magnesia. This mineral and some of its varieties is still under investigation, and, on this account I reserve further details of my analyses.

Churchite, $5\text{CeO}\cdot\text{CaO}\cdot 2\text{P}_2\text{O}_5\cdot 8\text{aq}$.—The discovery of this species in 1864 was also the discovery of the occurrence of cerium in England. The mineral, which occurs in definite crystals of hardness 3, and density about 3·14, is also new to science. It is of Cornish origin, and occurs with quartz in a copper lode. The chief metallic constituent of the species, though put down as cerium, really contains lanthanum and didymium as well. The mean results of analysis are as follows:—

	Experiment.	Theory.
CeO	51·87	52·73
CaO	5·42	5·47
P ₂ O ₅	28·48	27·73
H ₂ O	14·93	14·07
	100·70	100·00

For further details see CHEM. NEWS, vol. xii., pp. 121, 183 (1865); *Journ. Chem. Soc.* (2), iii., p. 259.

Cornwallite, $\text{Cu}_3\cdot 2\text{AsO}_4\cdot 2\text{CuH}_2\text{O}_2\cdot \text{aq}$.—The hitherto accepted formula for this very rare cupric arseniate was founded upon two incomplete analyses. By numerous analyses of three good specimens I succeeded in proving that two-fifths of the water assumed in the formula was not really present. Since my new analyses were published I have confirmed the views there stated by fresh studies, both chemical and microscopical, of the mineral. For details see *Journ. Chem. Soc.* (2), vi., 276.

Delvauxite, $\text{FePO}_4\cdot\text{FeH}_3\text{O}_3\cdot \text{aq}$.—This formula represents the composition of delvauxite (from Liege) freed from hygroscopic water by desiccation over sulphuric acid *in vacuo*. Dried at 100° the mineral loses one atom of water, and has then the formula of dufrenite. The older analyses of delvauxite gave most discordant results as to its percentage of water.*

Dufrenite, $\text{FePO}_4\cdot\text{FeH}_3\text{O}_3$.—Previous to some analyses of dufrenite which I made in 1864 the formula of dufrenite was unsettled, owing to the difficulty of obtaining samples for analysis free from the matrix of hæmatite, and to the obstinacy with which a portion of the constituent water is retained.†

Hisingerite, $\text{Fe}_2\text{O}_3\cdot 2\text{SiO}_2\cdot 2\text{aq}$; or $5\text{Fe}_2\text{O}_3\cdot 9\text{SiO}_2\cdot 8\text{aq}$.—This species was discovered for the first time in Cornwall last year. The analytical results of previous examinations of this substance have been rather variable, partly owing to the hygroscopic water present. *In vacuo*, over sulphuric acid, the powdered mineral lost in one instance 28·65 per cent of water, and at 100° only 0·54 per cent.‡

Limnite, $\text{Fe}_2\text{O}_3\cdot 3\text{H}_2\text{O}$; or $\text{Fe}_2\text{H}_6\text{O}_6$.—This species is the normal ferric hydrate, and very rarely occurs in a pure condition. A singularly clean specimen, of a stalactite form, from the Botallack Mine gave me the percentages which are compared below with those demanded by theory.

	Experiment.	Theory.
Fe ₂ O ₃	73·73	74·8
H ₂ O	24·40	25·2
Loss	1·87	—
	100·00	100·0

For details see *Journ. Chem. Soc.* (2), iii., p. 214; Dana's "Mineralogy," 5th ed., p. 178.

Melanconite, CuO .—Some black crystals, of density 5·83, embedded in a greenish matrix were found in Cornwall; they were handed to me by Mr. Talling. They proved to be pure cupric oxide. Professor Maskelyne has determined them to belong to the oblique prismatic system.*

Namaqualite, $\text{Al}_2\text{H}_6\text{O}_6\cdot 4\text{CuH}_2\text{O}_2\cdot 4\text{aq}$.—This mineral from Namaqualand, South Africa, belongs to the rare class of hydrous oxides in which a protoxide and sesquioxide are united. It occurs in fine blue silky crystals.†

Pagodite.—Without attempting to assign a formula to the particular kind of Chinese "figure-stone," which seems to me to belong to the pagodite analysed by Walmstedt and Brush (Dana, p. 455), I may add the following analytical results to those already on record in the hope that the chemistry of the various minerals often included under agalmatolite may become ultimately more definite; a greenish grey Chinese figure-stone, of hardness 2·5 and density 2·8, gave, on analysis, the following mean percentages:—

Al ₂ O ₃	31·06
SiO ₂	62·25
H ₂ O	4·66
Fe ₂ O ₃	0·82
MgO	0·60
	99·39

Restormelite.—Under the names of lithomarge, agalmatolite, or steatite, a massive greenish grey mineral, found in some abundance in the iron mine of Restormel, has been from time to time described. Its density is 2·58, its hardness 2. It differs from pinite by containing 12 instead of 6 per cent of water; it differs from halloysite by the presence of 7 per cent of alkalis. It seems to me to present evidence of being derived from a felspar; but, if so, the decomposition has not been complete. I hardly like to assign the rank of a species to restormelite, but, whatever the position ultimately assigned to it, a distinct name is necessary.‡

Tallingite, $\text{CuCl}_2\cdot 4\text{CuH}_2\text{O}_2\cdot 4\text{aq}$.—This mineral, which I first detected and analysed in 1865, is ranked by some mineralogists as a sub-species or as a variety of atacamite. Besides possessing a different composition, with a different colour and other physical characters, it appears to have that definiteness and constancy of composition without which a non-crystalline mineral is regarded with suspicion.

	Experiment.	Theory.
Cu	10·11	22·55
Cl	11·33	
CuO	53·57	53·29
H ₂ O	24·99	24·16
	100·00	100·00

Another blue hydrated cupric oxychloride from the same mine, Wheal Cock, near Botallack, Cornwall, was found to be still more basic than tallingite.||

Tasmanite, $\text{C}_{40}\text{H}_{62}\text{O}_2\text{S}$.—A fossil resinoid substance, of brown-red colour, occurring to the extent of 30 to 40 per cent in a shale from the River Mersey, Tasmania. It is supposed to have been originally the spore cases of some cryptogam; its hardness is about 2·0 and its density 1·18. The analytical percentages follow:—

S	5.32 ..	5.28
	100.00	100.00

For further details, *Phil. Mag.* (4), xxviii., p. 465.

Tavistockite, $\text{Ca}_3\text{P}_2\text{O}_4\text{Al}_2\text{H}_6\text{O}_6$.—This mineral, occurring in minute white acicular crystals with quartz, pyrites, chlorenite, &c., has been found near Tavistock, and at Stenna Gwyn. It might be mistaken for pharmacolite. It gave on analysis—

	Experiment.	Theory.
CaO	36.27 ..	35.97
Al ₂ O ₃	22.40 ..	22.06
P ₂ O ₅	30.36 ..	30.41
H ₂ O	12.00 ..	11.56
	101.03	100.00

For analyses see *Journ. Chem. Soc.* (2), iii., p. 263.

Woodwardite, $3\text{CuSO}_4.8\text{CuH}_2\text{O}_2.3\text{Al}_2\text{H}_6\text{O}_6.6\text{aq}$.—This Cornish species is near Lettsomite (Cyanotrichite). It occurs in minute botryoidal concretions of a rich turquoise or greenish blue colour. In composition it is perfectly definite and constant, but Professor Maskelyne considers it to be allophane, which contains 20 per cent of silica, though the new mineral merely contains traces (about 1 per cent) of that substance. On the other hand, M. Pisani considers it impure langite, assigning as his reason for this view that another mineral occurring in the same mine, of a dirty green colour and obviously mixed character (some specimens being made up of nine* different layers), was of indefinite constitution. It is unnecessary to combat these views.

ON THE

ACTION OF SULPHURIC ACID ON DIALLYL.

By WILLIAM ROBERT JEKYL.

Dalton Chemical Scholar in Owen's College.

DIALLYL was first prepared by Berthelot and Luca in 1856. They found that it dissolves in concentrated sulphuric acid with the evolution of much heat, and that after some hours an oil separates, which appears to be modified hydrocarbon.

In 1866 Schorlemmer published a paper on a new series of hydrocarbons derived from coal tar, having the formula $(\text{C}_6\text{H}_{2n-2})_2$ (*Proc. Roy. Soc.*, xv., 132). He there says, "As these hydrocarbons were obtained by the action of sulphuric acid on coal tar oils boiling below 120°, and as they differ by C_2H_4 , it appears to me almost certain that they are polymers of the hydrocarbons of the acetylene series, $\text{C}_6\text{H}_{2n-2}$, formed in the same way as diamylene is formed by treating amylene with sulphuric acid. In order to test this theory I have made some experiments with the two isomers C_6H_{10} , viz., diallyl and hexylene. By acting with sulphuric acid on these compounds, I obtained, besides large quantities of tarry matter, polymeric modifications boiling above 200°, having a smell similar to the hydrocarbons described above, giving also similar nitro-compounds; but the quantities which I got were not large enough for a more exact examination." With a view to throwing light upon this point, at the request of Mr. Schorlemmer I undertook to investigate the action of sulphuric acid on diallyl. The diallyl used was obtained by the action of sodium upon allyl iodide and boiled at 59°. Since concentrated sulphuric acid acts with great violence upon diallyl, the latter was diluted with about an equal bulk of pure paraffins boiling at from 55° to 60°. To

this mixture sulphuric acid was gradually added in small quantities, the bottle being frequently shaken. At the end of the reaction the contents of the bottle were found to be arranged in two layers, of which the upper one consisted of unaltered paraffins, and the whole of the diallyl having been taken up by the acid. The heavier and acid portion was diluted with water, when a dark coloured oil lighter than water separated out, and the whole was distilled from a large flask. The distillate consisted of a light oil, which came over below 100°, mixed with a little water. After a second solution in sulphuric acid and a repetition of the foregoing processes, in order to remove all traces of the paraffins, the oil was dried over calcium chloride and heated for some hours over potassium. The oil was thus obtained pure and boiled constantly at 93°. Analysis showed that its composition is expressed by the formula $\text{C}_6\text{H}_{12}\text{O}$.

This substance is readily soluble in concentrated sulphuric and fuming hydriodic acids, and slightly so in water. It is unacted upon by either caustic potash or potassium, and possesses a strong ethereal odour like that of peppermint. In presence of potassium bichromate and sulphuric acid, it yields a blue colour, similar to that produced by perchromic acid and common ether.

This compound has already been obtained by Wurtz (*Ann. Chim. Phys.*, (4), iii., 174), by treating di-iodhydrate of diallyl with silver oxide. He calls it diallyl monohydrate, but says further on that this body comports itself as an oxide or anhydride (ether), corresponding to dihydrate of diallyl, $\text{C}_6\text{H}_{12} \cdot \text{O}_2$, standing to the latter in the same relation as hexylene oxide to hexylene glycol, and might be called therefore *hexylene-pseudoxide*. As I have shown that the body is not acted upon by potassium, this view of Wurtz's is correct—it cannot be a hydrate, and I therefore propose to adopt Wurtz's second name, and to call it pseudoxide of hexylene.

To throw some light on its constitution it was oxidised by heating it in sealed tubes with a solution of potassium bichromate and sulphuric acid. On opening the tubes carbonic acid was evolved. Their contents were distilled, and the distillate neutralised with sodium carbonate. The neutral sodium salt was heated in a retort with sulphuric acid, by which means a distillate was obtained, which furnished a silver salt. The following analysis shows the salt to be silver acetate:—

Found.	Calculated for silver acetate.
64.41 per cent silver.	64.67 per cent silver.

The mother-liquor likewise furnished silver acetate.

Repeated experiments showed that nascent hydrogen evolved from sodium amalgam is without action upon hexylene pseudoxide.

Hydriodic acid acts upon the pseudoxide even in the cold. A few grammes of the substance were heated at 100° with an excess of fuming hydriodic acid in sealed tubes for about four hours. A red heavy liquid formed at the bottom of the tubes, the contents of which were distilled from a retort in presence of a little phosphorus. The iodide in the distillate was separated from the water, dried over calcium chloride, and distilled under a partial vacuum. On distillation, much decomposition ensued, with the formation of hydriodic acid, a little free iodine, and with the separation of tarry matter. After a second distillation *in vacuo*, and drying over caustic potash, a liquid was obtained, boiling under the ordinary pressure of the atmosphere, at 165° to 167°, which is the boiling-point of the β hexylic iodide of Wanklyn (*Chem. Soc. Journal*, 21).

Several iodine determinations, made by means of an alcoholic solution of nitrate of silver, further shows the substance to be hexyl iodide.

Found.	Calculated for $\text{C}_6\text{H}_{13}\text{I}$.
(1) 59.43	(2) 59.68 per cent iodine.
	59.90 per cent iodine.

In order to convert hexyl iodide derived from hexylene pseudoxide into hexyl hydride, Schorlemmer's method was

* *Journ. Chem. Soc.* (2), iv. p. 130.

† Read before the Literary and Philosophical Society of Manchester, October 18th, 1870.

employed. The oil obtained by this means contained but little olefines, and after purification boiled constantly at 68° to 69° . The following results of analysis show that it consisted of hexyl hydride.

	Found.		Calculated for C_6H_{14} .
	(a)	(b)	
C	83.49	83.35	83.72
H	16.30	16.42	16.28
	99.79	99.77	100.00

A portion of this hexyl iodide was oxidized by heating it in a flask attached to an upward condenser with a solution of bichromate of potash and sulphuric acid. During the operation much carbonic acid was liberated. The condensed acid was rendered neutral by sodium carbonate. From the sodium salt thus formed the acid was fractionated from a retort by adding successively five drops of sulphuric acid. From the first four distillates silver salts were obtained which furnished the following results on analysis.

	Found.		Calculated for silver acetate.	
	59.36 per cent silver.		64.67 per cent silver.	
(1)	59.36	per cent silver.	64.67	per cent silver.
(2)	66.63	" "	" "	" "
(3)	64.13	" "	" "	" "
(4)	64.66	" "	" "	" "

The non-agreement of No. 1 with the calculated results was owing to the fact that the salt was very impure and uncrystalline, nor could I succeed in purifying it by re-crystallisation. From distillates No. 2 and 4 similar results were obtained from salts, which crystallised from the mother-liquors. A second series of experiments, in which a weaker oxidising solution was employed, also yielded carbonic and acetic acids as the products of oxidation. It is of interest that the hexyl iodide, which was obtained from hexylene pseudoxide, and the boiling-point of which resembled that of Wanklyn's β hexylic iodide, yielded carbonic and acetic acids as oxidation products, while the β iodide yields, on the other hand, butyric acid in addition.

The diluted sulphuric acid, which had been used for acting upon diallyl, was neutralised with barium carbonate, filtered and evaporated to dryness, but no organic sulpho-acid had been formed.

Polymers of Diallyl.—After distilling off the hexylene pseudoxide from the diluted acid, a layer of hydrocarbons remained on the top of the liquid, from which they were separated by means of a stop-funnel. The hydrocarbons were dried over calcium chloride, and found to boil at between 200° and 300° . After several distillations over metallic sodium, they were separated into three portions, boiling at from 205° — 215° , 240° — 245° , 275° — 285° . These hydrocarbons invariably left a slight residue on distillation. Analysis showed that they have an empirical formula of C_6H_{10} .

(1) Boiling-point 205° — 215° .

	Found.		Calculated for C_6H_{10} .
	(a)	(b)	
C	87.31	87.38	87.8
H	12.52	12.31	12.2
	99.83	99.69	100.0

(2) Boiling-point 240° — 245° .

	Found.		Calculated for C_6H_{10} .
	(a)	(b)	
C	87.30	87.30	87.8
H	12.42	12.31	12.2
	99.72	99.61	100.0

(3) Boiling-point 275° — 285° .

	Found.		Calculated for C_6H_{10} .
	(a)	(b)	
C	86.96	87.8	87.8
H	12.81	12.2	12.2
	99.77	100.0	100.0

No. 3 attacked sodium slightly, although it had been distilled over it several times, therefore it is probable that its non-agreement with the calculated result was owing to admixture with an oxygen compound. From the above analysis and boiling points, it is probable that at least two polymers of diallyl are formed by the action of sulphuric acid upon it. I had not, however, a sufficient quantity of the hydrocarbons to obtain satisfactory vapour density determinations, which would at once have settled the point. It is nevertheless probable that No. 1 consists of two molecules of diallyl condensed into one, and that it has the formula $C_{12}H_{20}$; for Schorlemmer, by the action of sulphuric acid on hydrocarbons boiling below 120° from cannell oil, obtained one which boiled at 210° , and the vapour density of which showed that its formula was $C_{12}H_{20}$.

In conclusion, I have much pleasure in tendering my thanks to Dr. Roscoe and Mr. Schorlemmer, for their kindness and attention to me throughout the whole course of this research.

PARTICULAR RAY UNDER EXAMINATION.

By JOHN BROWNING, F.R.S.

In spectroscopes of ordinary construction, when several prisms are employed, a great deficiency of light will be noticed towards the more refrangible end of the spectrum.

This arises from the fact that the prisms are adjusted to the minimum angle of deviation for the most luminous rays which occupy the middle of the spectrum. The effect of this is shown in Fig. 1, P P.

In Fig. 1, P P, &c., represent a train of prisms adjusted, as I have just described, for the central portion of the spectrum, and screwed firmly in their places. T represents a telescope, moving round a centre situated at K. In the position in which the telescope is placed, the whole field of the object-glass would be filled with the green light of the spectrum issuing from the last prism; but, when the telescope is removed to the position shown by the dotted lines, either nearer to K or to V (in which case the red end or the violet end of the spectrum would be in the field of view), then, as we see by the lines, only a small portion of the spectrum would fall on the object-glass. But, it is obvious that, owing to the deficiency in light at the extreme ends of the spectrum, it is just in these very positions that it is desirable that the whole field of the object-glass should be filled. Now this can only be effected when the prisms are adjusted to the minimum angle of deviation for the particular portion which is being examined of the spectrum, and this it will be if the adjustment I have spoken of has been correctly made. This difference of adjustment is much more than is generally supposed, varying, in accordance with the refractive index of the glass employed, between 10° and 20° for the extreme portions of the spectrum.

Fig. 2 shows the method in which the change in the adjustment of the prisms to the minimum angle of deviation for each particular ray is made automatically.

In this diagram, P P, &c., as before, represent prisms. All these prisms, with the exception of the first, are unattached to the plate on which they stand, the triangular stand on which the prisms are hinged together at the angles corresponding to those at the bases of the prisms.

To each of these bases is attached a bar, B, perpendicular to the base of the prisms. As all these bars are slotted and run on a common centre, the prisms are

brought into a circle. This central pivot is attached to a dovetail piece of two or three inches in length, placed on the under-side of the main plate of the spectroscope; which is slotted to allow it to pass through. On moving the central pivot, the whole of the prisms are moved, each to a different amount in proportion to its distance in the train from the first or fixed prism on which the light from the slit falls after passing through the collimator, c. Thus, supposing the first prism of the train opposite c, represented in the diagram, to be stationary, and the second prism to have been moved through 1° by this arrangement, then the third prism will have moved through 2° , the fourth through 3° , the fifth through 4° , and the sixth through 5° . As these bars are at right angles to the bases of the prisms, and all of them pass through a

itself, and thereby the whole field of the object-glass is filled with light.

Thus the apparatus is so arranged that on turning the micrometer-screw, so as to make a line in the spectrum coincide with the cross wires in the eye-piece of the telescope, the lever, L, attached to the telescope and prisms, sets the whole of the prisms in motion, and adjusts them to the minimum angle of deviation for that portion of the spectrum.

Figs. 3 and 4 represent the appearances presented when looking through the telescope from which the glasses have been removed; in diagram 3 it will be seen that the whole circle of the object-glass is filled with light, as I have just described is the case with the new arrangement; while diagram 4 shows the effect of moving

FIG. 1.

FIG. 2.

FIG. 3

FIG. 4.

common centre, it is evident that the bases of the prisms are at all times tangents to a common circle.

Now for the contrivance by which this arrangement is made automatic. A lever, L, is attached to the corner of the triangular plate of the last prism. This lever by its further end is attached to the support which carries the telescope through which the spectrum is observed.

Both the telescope and lever are driven by the micrometer screw, M. The action of the lever is so adjusted that when the telescope is moved through any angle it causes the last prism to turn through double that angle.

The rays which issue from the centre of the last prism are thus made to fall perpendicularly upon the centre of the object-glass of the telescope, T, and thus the ray of light travels parallel to the basis of the several prisms, and ultimately along the optical axis of the telescope

the telescope through the angle in front of the fixed prism.

About three years ago I showed a rough model of the plan I have now described to Mr. Gassiot, for whom I made the large spectroscopy which was for some time in use at Kew Observatory.

Mr. Gassiot immediately asked me if I would apply this arrangement to his large spectroscopy. As I did not at that time see my way to make it self-acting by connecting the prisms with the micrometer-screw, I did not feel impelled to carry out the matter at once, owing to the fact that, about this time, the mapping of the solar spectrum, with the large spectroscopy in question, was discontinued. I also felt that, with the munificent liberality for which Mr. Gassiot has distinguished himself, he had simply asked me to add this contrivance to his large and costly

instrument in the interest of science generally, and not with any view to its immediate use.

Since this time, and particularly while I was constructing his solar spectroscope, Mr. Norman Lockyer has repeatedly urged upon me the desirability of completing the arrangement, and from the manner in which it has been received by the distinguished scientific men who have done me the honour to examine it minutely, I am induced to hope that its application will tend to facilitate further researches in spectrum analysis.

The instrument I have had the honour to describe possesses some special advantages for chemical investigations. Professor Roscoe no sooner saw it than he suggested that I should observe the ultra-violet rays of aluminium with it. These it showed to great perfection.

It may well be that careful researches made by its aid on spectra of various bodies might lead to the detection of elements as yet unknown.

SODIUM AS A FLUX FOR MINERALS.

By Dr. SCHONN.

A STEEL crucible $1\frac{1}{2}$ inches deep and the same in diameter is heated over a lamp; into this is projected a few pieces of metallic sodium, and afterwards the finely-divided and dry mineral is added. The crucible is then covered and heated red-hot. As soon as the reaction is finished the contents of the crucible are allowed to cool, and water is cautiously added, sufficient for the purpose of filtration. The fused mass is then thrown upon a filter and thoroughly washed. In the filtrate will be found the electro-negative constituents of the mineral combined with the sodium, such as sulphur, cyanogen, chlorine, chromic acid, silica, molybdic and tungstic acids, and such oxides as are soluble in soda-lye. On the filter will be found the metals and their oxides, also the lower oxides of titanium, molybdenum, tungsten, and possibly silica and alumina. The contents of the filter and the solution in the filtrate can be further treated according to the order of analysis. In this way all minerals can be readily resolved, and their constituents determined either qualitatively or quantitatively.

CORRESPONDENCE.

NEW ELECTRO-DYNAMIC LAW.

To the Editor of the Chemical News.

SIR,—Will you allow me to announce in your journal a new and important electro-dynamic law or laws. The reasonings and experiments, by which they are supported, I hope to enter on more fully in the next number of the *Quarterly Journal of Science*. Meanwhile, I submit them to the judgment of physicists for examination and approval, or otherwise.

1. In every galvanic circuit, the net heat produced by the chemical decomposition is divided into three parts—(a) due to merely local action arising from the impurities in the positive metal, or the re-formation of water from the nascent hydrogen; or (b) that which circulates through the battery and all other parts of the circuit, and which varies as the electro-motive power of the negative element in relation to the electro-positive; and (c) the residue which remains in the battery.

2. That part which circulates through the whole circuit is distributed in each part of the circuit, including the battery, in simple proportion to the resistance of each part.

These laws are thus expressed mathematically:—

Let H = total net heat produced;
 H_1 = heat produced by waste local action on the positive metal;

H_2 = the quantity put into circulation;

H_3 = the residue not put into circulation.

Then, of course—

$$H = H_1 + H_2 + H_3;$$

$$\text{and } \frac{H_2}{H_2 + H_3} = E,$$

E being the electro-motive force of the negative element in relation to the positive element used.

Also, if $H(b)$ be the total heat evolved in the battery when the circuit is closed;

$$h(b) = H_1 + H_3 + H_2 \frac{R}{R + r}$$

$$h(w) = H_2 \frac{r}{R + r}$$

and if $r(1), r(2), r(3)$, be the resistance of different parts of the circuit;

and $h(1), h(2), h(3)$, the heat evolved in those parts;

$$h(1) = H_2 \frac{r(1)}{R + r}$$

$$h(2) = H_2 \frac{r(2)}{R + r}$$

and so on.

$$\text{Again, if } H(3) = 0 \text{ or } \frac{H_2}{H_2 + H(3)} = 1$$

then the electro-motive power of the negative element is perfect as relates to the electro-positive element.

In a circuit of zinc in sulphate of zinc, and copper in sulphate of copper, $E = 1$, or the whole heat produced, is transmitted; with zinc, strong sulphuric acid, and platinum, $E = \text{about } \frac{1}{2}$, but varies with the strength of the acid; with iron in sulphate of iron, and copper in sulphate of copper, $E = \text{about } \frac{1}{3}$; with copper in nitrate of copper, and silver in nitrate of silver, $E = \text{about } \frac{1}{4}$.

The total electro-motive force of a couple depends partly on the net heat evolved, partly on the proportion of it transmitted through the circuit. The former depends principally on the positive element, the latter on the negative element.—I am, &c.,

MR. CHURCH'S PROCESS OF PRESERVING STONE.

To the Editor of the Chemical News.

SIR,—In your journal of last week I find the text of a paper, by Mr. A. H. Church, which was read at the Liverpool meeting of the British Association. Mention is made therein of a complex system of treating stone, which has been patented as a new invention, and recently applied upon certain portions of the Houses of Parliament. The method consists in washing the stone surfaces with three solutions successively applied: (1st) superphosphate of lime, now called "mono-calcic phosphate;" (2nd) baryta, or "barium hydrate;" (3rd) dialysed solution of silica.

It is my purpose now to show that this so-called new process is but a modification of that applied by myself on the Houses of Parliament in April, 1864, with points added, which may have been derived from other previously published sources. The dialysed silica solution is that of which the preparation and specific employment for these purposes was first described by yourself in November, 1861. (*CHEMICAL NEWS*, vol. iv., p. 227.) And, the superphosphate of lime, mixed with a little baryta for the purpose of decomposing the sulphates in the stone, was the solution actually employed by myself in the competitive trial at Westminster. Your readers are, therefore,

in a position to judge for themselves of the novelty of Mr. Church's improved process, which, by some unaccountable aberration, stands now patented in the name of Frederick Ransome.

I have only to add that I felt it my duty to address a letter upon the subject to the First Commissioner of Her Majesty's Works, protesting against this practical adoption of my process by a fellow competitor, immediately it became known to me that a trial of Mr. Church's triple plan had been sanctioned.—I am, &c.,

JOHN SPILLER.

London, Nov. 1st, 1870.

MISCELLANEOUS.

Spectrum of the Aurora.—We hear from Professor A. H. Church, of the Royal Agricultural College, that he was able to observe the spectrum of the aurora as seen at Cirencester on the 24th and 25th ult. He saw a steady yellowish green line, and frequently a brilliant red line near that of calcium. A pale line was also seen in the green, and a more definite one in the blue—these last not being constant in occurrence. The observations were made each evening between 6.30 and 8.30 p.m.

Apparatus for Maintaining Constant Temperatures in Laboratory Operations.—Messrs. Mottershead and Co. have just brought out an improved automatic regulator which is applicable to any operation in which gas is used as a source of heat. When fitted to copper drying closets or air baths the temperature may be limited to any degree from 75 F. upwards. This apparatus acting automatically, the temperature is unaffected by varying pressure of gas, the common source of accident in ordinary drying closets. Drying closets and evaporating basins are also fitted on a slightly modified plan, in which a reservoir of air placed *inside* the oven is made to act on the regulator, thus avoiding the necessity of a double copper chamber, and at the same time forming a sufficiently sensitive apparatus for many practical purposes.

The Photographic Exhibition.—The members of the Photographic Society will assemble at the Architectural Gallery, No. 9, Conduit Street, on Tuesday evening next, for the purpose of inaugurating their new session by the holding of the Fifteenth Annual Exhibition of Photographs. On the following day the galleries will be thrown open to the public, and continue so daily from 9 a.m. till dusk (Saturdays excepted) until the end of the month. The members have reserved to themselves and friends the right of free admission during the three Saturdays falling within this period, but the general public will, even on these days, be admitted on the usual terms of payment. In addition to the more ordinary productions of photography there will be exhibited examples of work done by the photo-mechanical printing processes of Herr Albert, MM. Ohm and Grossman, Mr. Woodbury, and others; besides a collection of photo-enamels, micro-photographs, reproductions, and enlargements.

Alloy known as "Tiers Argent."—Dr. C. Winkler.—The author says this alloy does not consist of $\frac{1}{3}$ of silver and $\frac{2}{3}$ of nickel, but was found, when analysed by him, to be made up of copper 59.06; silver, 27.56; zinc, 9.57; nickel, 3.42; total, 99.61.

Condensation of the Nitrous Vapours in the Manufacture of Sulphuric Acid.—R. Heilmann and P. Hart.—The vapours are condensed by means of water, wherein lime or magnesia are suspended, and the liquid thus obtained is either (a) first evaporated to dryness, and the residue ignited; or (b) heated to the boiling point, with addition of hydrochloric or sulphuric acid; or (c) evaporated to dryness, and the residue mixed with the residues of the manufacture of chlorine, and heated to a gentle red heat; in either of these three cases the nitrous vapours are again utilised in the leaden chambers.

Indelible Black Ink.—H. Puscher.—Dissolve 1 drachm of aniline black in 5 drachms of strong alcohol, to which add some 60 drops of pure and strong hydrochloric acid; next add a hot solution of $1\frac{1}{2}$ drachms of powdered gum arabic in 3 fluid ounces of water. Writing made with this ink is indelible by chlorine, oxalic, nitric and hydrochloric acids, and caustic potassa.

Prevention of the Spontaneous Combustion of Coals.—Dr. A. Lachmann.—In order to prevent as much as possible the chances of spontaneous combustion of coal on board ships and in the coalbunkers of steam-vessels, the author advises: to select coal as much as possible free from brasses (iron pyrites); to load the coal rapidly, and in as dry a state as possible; to stow them on board properly, but not too closely; to prevent, as much as possible, all access of air and water, and to sprinkle them with thin coal tar.

Induline, a new Blue Dye Material.—R. Knosp.—The author states, unfortunately, nothing about the nature, nor anything about the manufacture, of what he calls induline. He says it is a new pigment which is readily soluble in water yielding therewith a reddish blue coloured solution, which can be at once applied for dyeing purposes; best, however, after the addition of some sulphuric acid, and at boiling heat. The author further states that induline will certainly become an excellent substitute for indigo vats, and be especially of value for the dyeing of wool.

Manufacture of Iodine from the so-called Chili Saltpetre (Nitrate of Soda).—Dr. A. Lachmann.—The author states that at Tarapaca, Peru, there are now obtained about 40 kilos. of iodine daily by means of a process which is described as follows:—The mother-liquors from the refining of the crude nitrate of soda are carefully mixed with a mixture of sulphurous acid and bisulphite of soda, whereby all the iodine present in the liquor is precipitated in the free state as a blackish coloured precipitate; the iodine thus deposited is next freed from adhering fluid by placing it in an earthenware vessel, at the bottom of which are placed several layers of clean sand, so arranged that the size of its grains decrease from the bottom upwards. On the top of this sand the wet iodine is put, the sand acting as a sponge to absorb the fluid. When the iodine has become dry, it is carefully removed from the vessel, but a thin layer of it is left on the sand; the crude iodine is refined by sublimation. The inventor of this process, a Frenchman named Thiercelin, has recently found that, instead of using sulphurous acid, it is more advantageous to employ nitrous acid, obtained in the shape of nitrite of potassa by the ignition of a mixture of 1 part of charcoal and 5 of nitrate of potassa; the nitrite obtained yields, when mixed with the mother-liquor, a precipitate containing some 80 per cent of iodine.

Fusing Iridosmine.—Mr. Moses G. Farmer, of Boston, has fused the native iridosmine by placing the natural grains in a groove in charcoal, and subjecting them to the action of a current of voltaic electricity from sixty large Bunsen cells, using large platinum wires to make contact with the ends of the groove. He obtained in this manner bars of perfectly compact metal, brittle and very hard. The operation was anything but pleasant, on account of the intense light emitted and the fumes of osmic acid, which attacked the eyes and nostrils, producing the phenomena of rose or hay fever, and sunburning the face. Mr. Farmer estimates the temperature of the fusion at about 10,000° F. The object of the experiment was to prepare a bar of the alloy for the purpose of electric illumination. On rendering it luminous by an electric current, he found that when near the melting-point one square inch of surface evolved light equal to 2800 candles, which threw shadows in broad daylight at noon, and produced excellent photographs. The same battery converted solid bichloride of iridium into fused metal as soft and ductile as platinum. An aluminium wire, conveying a current

which raised it to near its fusing point, became perfectly flexible, like a hempen cord, being fused within, but preserving its continuity by its crust of oxide. A steel point thrust into it drew out the fused metal in threads.—*American Chemist.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Zeitschrift für Chemie von Beilstein, No. 15, 1870.

The original papers and memoirs contained in this number are—

Products of the Oxidation of Durol.—P. Jannasch.—This paper is the first part of a series on this subject, the portion before us treating on cumylic acid. When durol is acted upon by nitric acid diluted with 2½ times its bulk of water, the result is the production of a third homologue of benzoic acid, an acid composed of—

which has been named by this author *cumylic acid*. It is insoluble in water, but readily soluble in ether and alcohol; soluble also, but with more difficulty, in benzol; crystallises in prismatic crystals; volatilises along with aqueous vapours; sublimable; fusing at 150°. The author briefly describes the lime- and baryta-salts of this mono-basic acid.

Bromo-Sulpho-Toluol.—H. Hübner and F. C. G. Müller.—This lengthy paper contains the description of a series of salts obtained by operating with a large quantity of crude bromo-toluol-sulphate of calcium, after having been purified. The formula of this salt was ascertained, by analysis, to be $(\text{C}_6\text{H}_4\text{Br}.\text{CH}_2.\text{SO}_2.\text{O})_2\text{Ca}$. It is an anhydrous salt, which admits of being heated to 230° without decomposition; it is soluble in 60 parts of water at 14°. From a concentrated solution the salt crystallises in large brilliantly-shining crystals. The lead, barium, strontium, copper, zinc, manganese, and sodium salts, obtained by double decomposition, are described at great length. The bromotoluol-sulpho acid, in free state, is a deliquescent substance. The sulphochloride, prepared from the above-named sodium-salt by means of chloride of phosphorus, constitutes a solid compound, fusing at between 25° to 35°, insoluble in water, very soluble in ether, and remarkably resisting decomposition. In perfectly pure state, it is possible to heat this substance to 200° without decomposition; but, at a higher temperature, sulphurous acid is given off, and at 260° the decomposition becomes tumultuous. The authors also prepared the sulphhydrate and the bisulphide of bromo-sulpho-toluol. The bisulphide is insoluble in water, fuses at between 75° and 78°, and is difficultly soluble in alcohol.

Presence of Cholesteroline in Suint.—E. Schulze.—By the term *suint* is understood that peculiar kind of grease which is naturally present in sheep's wool. This raw material the author extracted from raw wool taken from sheep at a farmyard near Weende, a locality in the neighbourhood of Göttingen, Prussia, Regierungsbezirk, Hanover, where is established an agricultural experimental station, to which is attached a chemical laboratory. The author operated upon 120 grms. of the raw suint, which was saponified, by which operation it was ascertained, as has also been stated by Dr. Hartmann, that suint does not contain any glycerides. A large portion of the suint (70 per cent) could not be saponified by the usual process (boiling with an aqueous solution of caustic potassa), and was therefore exhausted from the soap by means of ether. After volatilisation of that fluid, the remaining fatty substance was treated, for a period of twenty hours, with an alcoholic solution of potassa in a closed vessel at 100°. After a series of operations (the aim thereof being to purify the complex fatty compound), the author obtained a crystalline mass, which was recognised as cholesteroline by the following reactions:—A small portion, having been rubbed up in a mortar with a few drops of concentrated sulphuric acid, yielded, after addition thereto of chloroform, a blood-red coloured liquid, which, after the addition of concentrated nitric acid, became first violet, next blue, and finally colourless. A small portion of the crystals was mixed, by the aid of a glass rod, with a liquid consisting of 3 parts, by bulk, of hydrochloric acid, and 7 part, by bulk, of solution of chloride of iron, and this mixture very gently evaporated to dryness; the undissolved mass assumed a violet-red hue, which soon turns to blue. A trace of the crystals was moistened with a drop of concentrated nitric acid, and gently evaporated to dryness; the remaining yellow speck, having been moistened with ammonia, assumed a red colouration. The anhydrous crystalline mass was found to fuse at 144.5° (dry and pure cholesteroline fuses, according to MM. Strecker and Hoppe-Seyler, at 145°). The results of the elementary organic analysis of this substance led to numbers which agree closely with

those of pure cholesteroline, the formula of which is $(\text{C}_{26}\text{H}_{44}\text{O})$. The author states that the cholesteroline in suint is mixed with substances on which he is engaged in further researches.

Chlorides of Sulphur.—H. Hübner and A. Gueront.—The authors first briefly allude to the well-known compound S_2Cl_2 , which boils at 136.5°, and consists of 47.41 per cent S and 52.6 per cent Cl. This chloride is capable of absorbing more chlorine, and forms a new compound, about which various views have been stated by several distinguished scientific chemists, in reference to its true constitution. The authors have therefore made the following experiments, with the view to reconciling the existing differences of opinion:—About 80 grms. of perfectly pure S_2Cl_2 were placed in a glass vessel, surrounded by a powerful freezing mixture, and saturated with perfectly dry chlorine; the excess of the latter was driven off by perfectly dry carbonic acid, previously saturated with the chloride of sulphur, (S_2Cl_2) . The newly-formed chloride, while remaining in the vessel surrounded by the freezing mixture, was sucked up in a previously accurately-weighed glass tube, which was sealed immediately afterwards, and again weighed. This having been done, the tube was carefully unsealed, and the contents immediately oxidised by means of pure and very strong nitric acid. The quantitative estimation of the chlorine and sulphur led to the following per cent results:—Sulphur, 31.07; chlorine, 68.93. The results of the researches on this subject may be summarised as follows:—There exist two definite compounds of chlorine and sulphur. One of these is a non-volatile chloride, Cl_2S , which, on being boiled, becomes decomposed in this manner:— $2\text{Cl}_2\text{S} = \text{S}_2\text{Cl}_2 + \text{Cl}_2$. The equivalent of Cl_2S is, the authors state, not determinable, on account of the non-volatility of this body; but they take that equivalent as equal to 103. The second chloride of sulphur, S_2Cl_2 , is readily formed from the other compound just alluded to, as elucidated by the formula above mentioned. The authors add that the results of their researches agree with and confirm those of M. Dumas on this subject.

Conversion of Allyl-Alcohol into Normal Propylic Alcohol.—B. Tollens.—This very closely-written paper contains chiefly the record of the fact, discovered recently by the author, that, when allyl-alcohol is treated with hydrate of potassa, there is obtained a considerable quantity of normal propylic alcohol, not mixed with isopropylic alcohol, when equal parts, by weight, of the two substances (viz., caustic potassa and allyl-alcohol) are operated upon. The author enters at length into the detailed description of a series of fractional distillation experiments and the substances thereby obtained, and concludes his memoir with the statement that his researches on this subject confirm the correctness of the following formula:—

Strychnine Oxethyl Compounds.—Drs. Strecker and Messel.—By heating, in a sealed tube, a mixture of one-fourth part, by weight, of epichlorhydrine, with strychnine, to a temperature of from 120° to 160°, the authors obtained strychnine-oxethyl-chloride, $\text{C}_{22}\text{H}_{27}\text{N}_2\text{O}_2\text{Cl}$, a body readily soluble in water, and crystallising from its solution in that liquid. The aqueous solution is not precipitated by ammonia; by a mixture of sulphuric acid and bichromate of potassa, the aqueous solution is temporarily coloured brilliantly violet. Chloride of platinum causes the precipitation of a magnificent orange-coloured double salt, $\text{C}_{22}\text{H}_{27}\text{N}_2\text{O}_2\text{Cl} \cdot \text{PtCl}_2$. The authors briefly describe, further, a strychnine-oxethyl-sulphate and a strychnine-oxethyl-hydrate, and state that strychnine behaves in a manner analogous to trimethylamine, while they conclude that the constitution of this new base is analogous to choline, and should be formulated thus:—

Sulpho-Maleinic Acid.—Drs. Strecker and Messel.—Maleinic acid, having been boiled with an aqueous solution of neutral sulphate of potassa, yields a new body, sulpho-maleinic acid, which, however, is only cursorily alluded to in this paper as to its properties in free state, there being only mentioned a series of salts, the neutral potassa salt being represented by $\text{C}_4\text{H}_4\text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$. The free acid was obtained by the decomposition of the silver-salt by means of sulphuretted hydrogen; it is a difficultly crystallisable solid body, which, on being heated with caustic potassa, yielded fumaric acid. The main conclusion the authors draw from their researches is the absolute identity of sulpho-fumaric, sulpho-maleinic, and sulpho-succinic acids.

Action of Ammonia upon Chloride of Thionyl and Chloride of Selenium.—Dr. A. Michaelis.—This very lengthy essay contains the exhaustive account of a series of researches instituted by the author with the view to test the correctness of the labours instituted on this subject by Dr. Schiff (*Ann. Ch. Pharm.*, vol. cii, p. 113, and vol. cxi, 93). The first portion of this paper treats on the action of ammonia upon thionyl-chloride; and the memoir, too lengthy for any useful abstraction, contains, further, the following sections:—Action of ammonia on selenyl-chloride; action of chloride of phosphorus upon selenious anhydride and upon selenyl-chloride.

Lime and Mortar.—W. Walters.—The author has experimented to obtain accurate information on the process of the hardening of lime and mortar, as applied for ordinary building purposes. The main results of these researches are the following:—The freshly applied mortar gives off, at first, water only, by which process the particles of lime begin to adhere together; afterwards, carbonic acid begins to be absorbed, and thereby the solidity of the mass is increased. The last stage of the drying of the mortar coincides with that of the saturation of the lime with carbonic acid; and this process causes the fixation of

the porous bricks with the mortar. The absorption of carbonic acid alone, without previous dehydration, never causes ordinary mortar to become hard. Freshly made mortar, exposed to an atmosphere of moist carbonic acid, remains soft; while mortar placed under a bell-jar filled with carbonic acid, and standing over a basin filled with strong sulphuric acid, becomes rapidly hard. Large quantities of mortar, especially with a limited exposure to air, take months, or even years, to become hard.

Estimation of Phosphoric Acid in Phosphorite's.—K. Birnbaum and C. Chojnacki.—The authors state that they apply, for the above-named purpose, a modification of Dr. G. Chancel's method, which admits of being carried out in about six hours, and gives good results. The analysis is performed as follows:—Take 2 grms. of the very finely pulverised mineral; put the weighed mineral into a flask, or beaker-glass, and pour over it about 7 c.c. of nitric acid free from any chlorine, and of 1.25 sp. gr. Heat the vessel and its contents for about half an hour nearly to the boiling-point, dilute with pure distilled water, and filter; add to the well-washed filtrate, as much water as will suffice to make up a quantity of 500 c.c. Take 100 c.c. of this liquid, representing 0.4 grm. of phosphorite; add another 100 c.c. of pure distilled water, heat to the boiling-point, and precipitate the hot fluid by the addition of a solution of nitrate of bismuth (prepared in the following manner:—Take crystallised nitrate of bismuth, dissolve in water; add as much nitric acid as is required to prevent precipitation on the addition of more water; make up the solution in such a manner as to obtain a litre of fluid containing 26 grms. of bismuth). The precipitate, occasioned by the addition of the bismuth solution to the solution of phosphorite, is left standing till quite cold, and is then filtered off, the precipitate being washed with cold water. Next, the phosphate of bismuth is dissolved, while on the filter, in a few drops of hydrochloric acid, and that solution is treated with ammonia and sulphide of ammonium, and gently heated, until all the bismuth has been converted into sulphide. When this has been effected, the liquid is acidified with acetic acid, and next heated to near the boiling-point; the precipitate is then collected on a filter, the last traces of sulphuretted hydrogen being eliminated by a few drops of chlorine-water. The phosphoric acid is estimated in the acetic acid solution by the well-known uranium process.

Different Methods of the Estimation of Manganese.—E. Escher and G. Rumpf.—The authors have tried comparatively, by means of a series of experiments, the following methods of the estimation of manganese:—Method of Fresenius and Will; method by which the manganese is placed in an hydrochloric acid solution of protochloride of iron, the quantity of non-oxidised iron being estimated; the method whereby, by the aid of hydrochloric acid, chlorine is developed from the manganese, and that gas taken up by hydrate of lime, followed by the estimation of the quantity of hypochlorite of lime thus produced; lastly, Bunsen's method, consisting in the evolution of chlorine from the manganese, and the passing of that gas into a solution of iodide of potassium, and estimation of the quantity of iodine set free. The authors found that only the methods of Fresenius and Will, and that of Bunsen, yield reliable results. They employed, for trial, the samples taken from one and the same large parcel of manganese, and state that the largest difference of the results obtained by applying the various methods several times were as follows:—

	Average.	Greatest difference between experimental results.
	per cent.	per cent.
Fresenius and Will . . .	63.50	0.04
With protochloride of iron . . .	62.06	1.15
As hypochlorite of lime . . .	60.90	5.24
Bunsen's method . . .	62.74	0.03

Analysis of Substances which on being Heated with Hydrochloric Acid yield Chlorine.—Dr. R. Fresenius.—In order to prevent the running back of the solution of iodide of potassium in the performance of Bunsen's titration method, the author proposes to prevent this by the addition of a few lumps of magnesite (compact native carbonate of magnesia) in the flask, the effect being the slow but steady evolution of carbonic acid gas, which, by the pressure it exerts, prevents the running back of the iodide of potassium solution.

Preparation of Pure Hydrochloric Acid.—Dr. R. Fresenius.—By means of direct experiments, the author has found that the method proposed by P. W. Hofmann for the preparation of pure hydrochloric acid (this method is not described, but it would appear to be based upon the driving off of hydrochloric acid gas from the crude acid as obtained in alkali works by the aid of heating with sulphuric acid, and the condensation of the gas thus set free in pure water), does not yield hydrochloric acid free from arsenic or free chlorine in case the crude acids, sulphuric and hydrochloric, employed, contain arsenic or the last named free chlorine.

Estimation of Phosphoric Acid as Ammonio-Magnesium Phosphate.—W. Heintz.—The main point of interest in this paper is, that the precipitate of ammonio-phosphate of magnesium, obtained in the generally known method of the estimation of phosphoric acid has to be re-dissolved in dilute hydrochloric acid after having been washed with dilute ammonia in order to get rid of a portion of the magnesia, which, in the first precipitate, is carried down, but not combined with phosphoric acid.

Estimation of Nitric Acid in Potable Water.—Dr. F. Goppelsröder.—The author states that having an opportunity to test Dr. Marx's plan of the estimation of nitric acid in water by means of an acid solution of indigo, he discovered that this plan yields too low results, while, moreover, the nitrites present in water are found to interfere with this process. This difficulty the author overcomes by making use of a titrated solution of permanganate of potassa applied to the water after the addition of a few drops of dilute sulphuric acid.

Preliminary Notice.—H. Hübner and C. Müller.—The authors state that they are engaged in experimenting upon the action of sodium upon epichlorhydrine; several new compounds are thereby formed, among which are the alcohols, $C_4H_9O_2$ and $C_6H_{11}O_4$; the authors give this brief notice because at present they are prevented from proceeding with these researches.

Annalen der Chemie und Physik, von Poggendorff, No. 8, 1870.

This number contains the following original papers and essays:—

Thermo-Chemical Researches.—J. Thomsen.—This paper is the continuation of the author's very lengthy essay on this subject, this present portion being divided into the following sections:—Researches on formic, acetic, oxalic, succinic, tartaric, and citric acids; researches on chromic, carbonic, and hydro-sulphuric acid; results of experiments relating to the neutralisation and basicity of the acids.

Researches on Electric Discharges.—W. v. Bezold.—This paper is illustrated with engravings absolutely required for the proper understanding of its contents; the results arrived at by the author's experiments may be summarised as follows:—When there are open to an electric discharge, after the breaking of an electric spark, two ways towards earth, one of which is longer than the other, the longer way being interrupted by a test-plate (Probeplatte), the result will be the division of the discharging current, if the distance the electricity passes before striking be small, but if that distance be large the electricity takes the shortest way, and carries even along with it the same kind of electricity from the longer way; if an electric current is conducted on to a wire insulated at its end, the electricity is reflected at that end, and there ensue a series of phenomena of alternating discharges; an electric discharge is carried through wires of the same length with the same velocity, irrespective of the material these wires are made of.

Electro-Motive Force of the Electric Light.—W. v. Bezold.—An algebraico-physical paper.

Caloric Capacity of Water when near its greatest Density.—L. Pfaunder and H. Platter.—This memoir contains essentially a lengthy series of results of experiments exhibited in a number of tables containing several columns of figures.

Acoustical Studies on Flames.—E. Villari.—A lengthy essay illustrated by a series of engravings.

Relation Existing between Transverse Contraction and Longitudinal Dilatation.—A mathematico-physical paper.

Compensation of an Optical Change of Phase.—J. L. Sirkis.

Reply to M. Most.—L. Boltzmann.—An algebraical paper, an observation also referring to the following.

Contribution to the Molecular Theory, and to the Doctrine of Electricity.—L. Lorenz.

Theory of Poisson Relating to the Temperature of the Globe.—O. Frölich.—A discussion on the value of certain algebraical formulæ put forward by M. Poisson to explain the phenomena of the disposition of the temperature over our globe.

Curious Effects Produced by Lightning.—Dr. J. G. Fischer.—The author describes at great length the effects caused by the lightning striking his house, a detached residence situated at a distance from Hamburg, on the 17th June last; the lightning first struck and demolished a stack of chimneys, and next found its way to the soil along a zinc pipe for conveying the rain-water from the roof downwards; the pipe alluded to, previously sound, was perforated in three places in a very curious manner; at one of the holes the metal was forced outward, while at the two other holes the metal had been forced inward in such a manner as to close the tube for the passage of water, at the point where the tube reached at the bottom the earthenware drain-pipe; the latter was smashed, the soil which covered it having been scooped out; no fire ensued by the striking of the lightning, nor was fusion of metal anywhere perceptible. The author enters into lengthy details on the magnetic action of the lightning upon steel and iron objects; none of the parties present in the house at the time of the occurrence were at all injured.

Relation of the Specific Heat of the Air when under a Constant Pressure and Volume.—Dr. Witte.—A short letter to the editor correcting some algebraical formulæ formerly published.

Minimum of Prismatic Aberration.—A. Kurz.

Preparation of a Fluid suitable for the Formation of Plateau's Equilibrium Figures without Gravity.—R. Böttger.—Take previously flaked palm-oil soap, place it in a large flask, and pour over it cold distilled water so as to prepare a cold saturated solution of soap, which should be filtered through grey filtering paper; there is next added about one-third part of the bulk of the fluid of pure concentrated glycerine; before using this fluid it should be well shaken up; the author states that soap bubbles of more than a foot diameter can be made with this fluid, and that such bubbles may be obtained attached to a piece of iron wire; if protected from currents of air the bubbles will persist for even ten hours.

Pharmaceutische Zeitschrift für Russland, No. 10, 1870.

This number contains the following original papers:—

Various Methods of Testing the Value of Opium, and more especially on the method prescribed for that purpose in the New Pharmacopœia of the Austro-Hungarian Monarchy.—A. Siersch.—This lengthy paper contains a review of the comparative value of the various methods proposed at different periods, and by different authors, for the estimation of the value of opium, as compared with

the method directed to be applied for this purpose by the pharmacopœia above mentioned.

Chemical Researches on the Fruits of the Laurel Plant.—Dr A. Casselmann.—We have already noticed this essay from another periodical. The essay itself is a separate work written in Russian.

NOTES AND QUERIES.

Love's "Dyer and Scourer."—Can any of your readers tell me where I can get the above work?—X. Y. Z.

Estimating Tartaric and Citric Acids.—Can you refer me to any work giving any recognised method of estimating tartaric and citric acids in the crude substances—argol, &c.?—A. J. M. EDGER.

Salaries.—"Student X." will feel greatly obliged if any reader of the CHEMICAL NEWS will give him some idea of the salary a B.Sc. Lond. Univ. might reasonably expect to receive for his services in an average laboratory, London or provincial.

Ethers in Wine.—(Reply to "H. T. B.")—The paper you refer to—viz., "Sur la Proportion des Ethers dans les Vins et sur quelques uns des Changements qui s'y Produisent," by M. Berthelot, is to be found in *Comptes Rendus des Séances de l'Académie des Sciences*, vol. lvii., pp. 231 and 287.

Aluminium in Batteries.—I have tried the metal aluminium as a substitute for platinum, in a Grove's battery, and the experiment is quite successful. Two small cells, the size of the Al plates being 4 inches by 14, decomposed water very energetically. The metal aluminium possesses the advantage of costing (for equal surfaces) about one-tenth the price of platinum. I obtained it, price 5s. per ounce, cut to size as ordered.—W. NETTLETON.

Tabachere.—(Reply to Wm. Lant Carpenter.)—Tabasheer, as it ought to be written, is a Persian word signifying a concretion found in the joints of the bamboo, *Bambusa arundinacea*, said by Dr. Russell to be the juice of the plant thickened and hardened, by others to be pure silica. It is valued, in the East Indies, as a medicine for the cure of bilious vomitings, &c., but its effects are more imaginary than real. It appears to be mainly composed of siliceous matter which the plant is unable to incorporate in its tissues; its peculiar optical properties have been described by the late Sir David Brewster.

Phosphate of Lime.—I should be glad to be informed of the formula and equivalents of a "bi-phosphate of lime" and "tri-phosphate of lime" respectively, anhydrous phosphoric acid being $P_2O_5 = 142$. In Williamson's "Chemistry" I find bi-phosphate given as $CaH_2P_2O_6 = 234$, and tri-phosphate, $Ca_3P_2O_6 = 310$, having the relation of 100:132.5, but in all analyses I have seen I find the equivalents taken as related to each other as 100:156 or 157. I should, therefore, be thankful to know the explanation of this apparent error. Is it connected with a professional or commercial usage?—W. TATE.

Deodorising Oil.—Sulphuretted Hydrogen Apparatus.—Can any of your correspondents inform "Nindex" (1) of a method for deodorising rape and colza oils? so as to fit them for use in perfumery, &c., where their peculiar odours are detrimental. Animal charcoal has been tried; its action is decidedly an improvement, but on rubbing the oil so treated between the hands the odour is then as persistent as before treatment. (2) What is the best form of H_2S apparatus for use in a small laboratory, opening on to a pharmacy where the public are continually coming in and going out, so as to prevent annoyance by its disagreeable odour. There is one figured by Fresenius and devised by Pohl; have any of your correspondents experience of the same, as that seems to be, theoretically, the best yet made known to me.—NINDEX.

MEETINGS FOR THE WEEK.

MONDAY, 7th.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action."
Royal Institution, 2. General Monthly Meeting.
TUESDAY, 8th.—Ethnological, 8.
Photographic, 8. Exhibition.
THURSDAY, 10th.—London Institution, 74. Dr. W. H. Stone, M.A., "On the Acoustics of the Orchestra."

TO CORRESPONDENTS.

J. W. M.—You will find the information you require in Richardson and Watts's "Chemical Technology."

M. M. P. M.—(1) *Proceedings of the Royal Society*. (2) Thompson's "History of Chemistry."

The Secretaries of the Ethnological and Photographic Societies are thanked for the cards of admission which they have been good enough to send.

T. Corbett.—A reply has been sent by post.

Post Office Irregularities.—Since the introduction of the halfpenny postage, the complaints of delay in the transmission of the CHEMICAL NEWS have become very numerous. Our subscribers may rest assured that in all cases the fault rests with the Post Office authorities, and complaints should be addressed to them. We suffer equally in the regularities in the receipt by post of our own periodicals.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 28s., 300 Illustrations.

Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE and Co., 20, King William Street, Strand.

Just published, pp. 60, price 2s., cloth 2s. 6d. (postage id.).

Elementary Questions in Chemistry (for Schools). First series. Thirty Papers on "Heat and Metalloids," by Thomas Wood, Ph.D., F.C.S., Lecturer on Chemistry at the Brighton and Lancing Colleges; author of "Chemical Notes," &c.

London: J. Helm, 10, Brownlow Street, Holborn, W.C.
Brighton: H. and C. Treacher, 1, North Street.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7, IRWELL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXII. No. 572.

ON A CONVENIENT FORM OF SPECTROSCOPE FOR USE IN A LABORATORY.

By JOHN BROWNING, F.R.A.S.

THIS spectroscope is so constructed that it may be kept in close proximity to a chemical laboratory without injury. The prism is provided with a cover, which should be put on with a little bees'-wax; or, better still, bees'-wax and tallow. This prism, with cover complete, can be removed and replaced without deranging the adjustment of the instrument, to allow of a bottle prism being substituted for the purpose of taking the refractive index or dispersive power of any liquid. The stand of the instrument is of wood, and the whole is enclosed in a circular cover which fits tightly round the base of the instrument, and has no other joint or opening.

REMARKS ON RICININE.

By RICHARD V. TUSON, F.C.S.,
Professor of Chemistry in the Royal Veterinary College.

AMONG the "Chemical Notices from Foreign Sources" which appeared in the CHEMICAL NEWS of the 21st of October last will be found an extract from an article entitled "On Ricinine and the Active Principles of Ricinus Seeds," published in the *Pharmaceutische Zeitschrift für Russland*, No. 1, 1870. This extract contains the following statement:—"As regards the ricinine of Dr. Tuson, prepared by the author (Dr. E. Werner) in large quantity, and according to Dr. Tuson's directions, it is stated that ricinine is not an alkaloid, and, moreover, a substance which contains a considerable quantity of ash; and the author, after carefully made analyses, comes to the conclusion that Dr. Tuson's ricinine is a compound of magnesia and of an organic acid, the formula of this body being—

That the bodies obtained by Dr. Werner and myself from castor seeds are totally different I hope to render evident in the present communication.

I have in my possession two small specimens of ricinine; one was prepared from the so-called castor cake obtained from India, the other from castor cake obtained from Italy. These specimens possess the undermentioned properties:—

1. Cautiously heated on a glass plate they melt and form a colourless mobile liquid, which, on cooling, solidifies into a whorl of acicular crystals.
2. Heated between two watch-glasses they sublime, apparently without decomposition.
3. Strongly heated on platinum foil, they first melt, then burn with a highly luminous flame, and leave no ash.
4. Heated with solid potassium hydrate, they evolve ammonia, proving that they contain nitrogen.
5. On estimating the amount of nitrogen by Péligot's method, the specimen of ricinine procured from Indian castor-cake contained 20.79 per cent, while that from Italian cake contained 20.39 per cent.
6. A solution of ricinine in hydrochloric acid mixed with one of platinic chloride yields, on evaporation, well defined orange octahedra.
7. Cold saturated aqueous solutions of ricinine and mercuric chloride, if mixed together and allowed to stand, deposit fasciculi of acicular crystals.

A comparison of the foregoing epitomised account of ricinine with the description of the magnesium compound obtained by Dr. Werner from ricinus seeds, therefore clearly indicates that the two bodies are entirely different.

That ricinine is entitled to the appellation of alkaloid I hope yet to demonstrate by its complete investigation so soon as I shall become possessed of a large supply of castor cake, now, I believe, on its way from Calcutta.

ON NEW ANALYTICAL PROCESSES.

By J. H. TALBOTT.

I. On the Precipitation of Zinc and Manganese as Sulphides.

ZINC is thrown down from cold solution by an alkaline sulphide in the form of a slimy mass which settles slowly and is extremely difficult to wash. The precipitation is, however, more complete than when sodic carbonate is used, and may be rendered very easy and rapid by the following process:—The solution of zinc, if acid, is to be neutralised as nearly as possible by sodic or ammoniac carbonate. To the boiling solution, sodic or ammoniac sulphide is to be added, a large excess being very carefully avoided. The white precipitate, on continued boiling, soon becomes granular, and settles readily. The supernatant, clear liquid is then to be tested with a drop of the alkaline sulphide, to be sure of complete precipitation, and the sulphide then washed with hot water by Bunsen's method. The filtrate is perfectly clear, and absolutely free from zinc; the washing is easy and rapid. The sulphide of zinc is then to be partially dried with the filter, in the manner recommended by Bunsen, brought into a porcelain crucible, and ignited, at first gently, and afterwards strongly, with free access of air. The expulsion of the last traces of sulphuric acid is much facilitated by occasionally dropping fragments of ammoniac carbonate into the crucible. Pure ZnO finally remains, the ignition being continued until a constant weight is obtained. In this manner the following results were obtained:—

gr.	gr.
0.3216 pure ZnO gave	0.3216 = 100.00 per cent
0.3208 " " "	0.3209 = 100.03 " "
0.2412 " " "	0.2410 = 99.91 " "
0.1785 " " "	0.1784 = 99.94 " "

In zinc sulphate, which had probably lost a little water—

gr.	gr.
0.6485 gave	0.1851 ZnO = 28.54 per cent.
0.6510 " " "	0.1858 " = 28.54 " "
0.8198 " " "	0.2338 " = 28.52 " "

The formula requires 28.29 per cent ZnO. The advantages of this process over the older methods of precipitating in the cold are, I think, very evident, even if only the saving of time be taken into consideration.

Manganese may be precipitated completely from its boiling solutions by precisely the same process. The flesh-coloured sulphide is granular, and sometimes even sandy, though not distinctly crystalline, and may be washed with the utmost facility. The precipitated sulphide, after washing upon a filter, is to be re-dissolved in chlorhydric acid, and precipitated as ammonio-phosphate in the manner proposed by Professor Gibbs. To test the method with a perfectly definite salt of manganese, manganous pyrophosphate was selected, dissolved in dilute chlorhydric acid, and the solution nearly neutralised by sodic carbonate. To the boiling solution, sodic sulphide was then added, and the manganese finally weighed—in one analysis as pyrophosphate, in another as anhydrous sulphide—by ignition in a current of SH_2 . In this manner—

0.3132 gr. $\text{Mn}_2\text{P}_2\text{O}_7$ gave 0.3126 gr. $\text{Mn}_2\text{P}_2\text{O}_7 = 49.56$ per cent MnO.

0.3786 gr. $\text{Mn}_2\text{P}_2\text{O}_7$ gave 0.2310 gr. $\text{MnS} = 49.65$ per cent MnO.

The formula requires 49.64 per cent MnO. It is, perhaps, worthy of notice that ammoniac sulphide does not completely decompose manganous pyrophosphate under the circumstances above described. The greater portion of the salt is precipitated at once as crystalline ammonio-phosphate of manganese.

II. On the Quantitative Separation of Tin and Tungsten.

The quantitative separation of tin from tungsten has always been regarded as a difficult problem not hitherto solved in a satisfactory manner. The following method will, I think, be found to leave nothing to be desired as respects both ease and accuracy. It depends upon the fact that stannic oxide, SnO_2 , is reduced by potassic cyanide with great facility; while tungstic acid, WO_3 , undergoes no reduction, even when heated with the cyanide to a high temperature. The oxides of tin and tungsten are to be heated in a porcelain crucible with three or four times their weight of commercial potassic cyanide, previously fused, pulverised, and thoroughly mixed with the two oxides. The mass is kept fused for a short time, when the tin separates in the form of metallic globules, while the tungstic acid unites with the alkali of the potassic cyanate and carbonate present. After cooling, the mass is to be treated with hot water, which dissolves the alkaline tungstate and other salts, and leaves the tin as metal. This is to be filtered off, washed, dried, and weighed as stannic oxide, after oxidation in the crucible with nitric acid. The tungstic acid is most conveniently estimated by the difference, but may of course be precipitated by mercurous nitrate, after boiling the solution with nitric acid to decompose the excess of potassic cyanide present, and then re-dissolving the precipitated tungstic acid by means of an alkali. To test the method, weighed portions of pure stannic and tungstic oxides were mixed and treated as above—

0.6662 gr. SnO_2 and 0.5880 gr. WO_3 gave 0.6679 gr. $\text{SnO}_2 = 53.24$ per cent. The calculated percentage of stannic oxide is here 53.11.

0.7098 gr. SnO_2 and 0.5460 gr. WO_3 gave 0.7096 gr. $\text{SnO}_2 = 56.51$ per cent, the calculated percentage being 56.52.

0.5378 gr. SnO_2 and 0.4373 gr. WO_3 gave 0.5405 gr. $\text{SnO}_2 = 55.43$ per cent, the calculated percentage being 55.15.

0.5073 gr. SnO_2 and 0.4334 gr. WO_3 gave 0.5081 gr. SnO_2 and 0.4349 gr. WO_3 . This corresponds to—

	Found.	Calculated.
Stannic oxide ..	54.01	53.92
Tungstic oxide ..	46.23	46.08
	100.24	100.00

As it might, perhaps, be objected to the examples given above that I employed only purely mechanical mixtures of stannic and tungstic acids, and that this is not the case which occurs in practice, I made the following additional analyses:—Portions of the two metallic oxides were fused in a silver crucible with pure sodic hydrate; the fused mass was then dissolved in water, and the two oxides precipitated together from the solution by nitric acid with the usual precautions. The ignited mixed oxides were then fused with potassic cyanide, as above. In this manner—

0.7292 gr. of a mixture of SnO_2 and WO_3 gave 0.4211 gr. $\text{SnO}_2 = 57.74$ per cent.

0.9826 gr. of the same gave 0.5661 gr. $\text{SnO}_2 = 57.61$ per cent.

Tin cannot be separated from molybdenum by fusing the mixed oxides with potassic cyanide, as the molybdic acid is always more or less completely reduced to a lower oxide.—*American Journal of Science.*

THE ISOMERS OF AMYL.

By HERBERT MCLEOD, F.C.S., &c.

HAVING been much interested by Mr. O. Loew's communication, "On the Number of Isomeric Bodies," which appeared in the *CHEMICAL NEWS* of Oct. 7, may I be permitted to point out that the number of isomers of amyl has been somewhat over-estimated? for in the series of formulæ given, several cases occur in which the same compound is repeated, though in a different form. Mr. Loew professes to discard what he names the "theory of agglomeration and of the so-called binding and linking of atoms," though in the next column he speaks of two atoms of the same hydrocarbon being connected by a diatomic "radical," and follows Professor Kolbe in considering the hydrocarbons to be analogous to diamines and triamines which have a well-defined constitution. He thus virtually concedes the principle that he pretends to eschew. These differences of opinion on the rational formulæ of compounds are often mere questions of words and expressions, the same facts being symbolised in different ways; the formulæ indicating the same arrangement of the atoms among themselves, though the symbolic representations at first sight appear to differ entirely. Mr. Loew's formulæ will be found, on inspection, to be based on what has been termed the quadri-valent or tetrad character of carbon, and this will be seen by comparing the following corresponding expressions which have been suggested by various chemists. In the first place will be found the formulæ of Mr. Loew; in the second, a kind of abridged graphic formula, now much used, in which the symbols of the atoms which are directly combined with one another are joined by hyphens or short strokes; and in the third, the notation proposed by Dr. Frankland (*Journ. Chem. Soc., N. S., iv., 372*), in which the grouping element is placed at the commencement of each line, and is directly combined with all the elements and radicals following it in the same line, the brackets indicating that the carbon atoms at the beginning of each line are directly combined with those above and below. To take the formulæ in the order in which they are placed in Mr. Loew's paper:

Isomers of Amyl. C_5H_{11} .
I. Monocarbolic Radicals.

a. Primary.

(It is by the last carbon in Mr. Loew's, and by the lowest one in the other two formulæ, that the radical is united to other radicals in amyl compounds; these are, consequently, semi-molecular formulæ, and represent unsaturated bodies.)

b. Secondary.

(In the last formulæ, it is the centre atom of carbon that unites with other radicals.)

c. Tertiary.

II. Dicarbolic Radicals.

These, we are told, resemble, in constitution, the diamines, two atoms of carbon being connected by a diatomic radical. As an example of a diamine, we will take ethylene-diamine—

which may be considered as a derivative of diammonia—

but the diamine may equally well be regarded as obtained from two molecules of ammonia—

by the substitution of the diatomic radical ethylene for one atom of hydrogen in each of the ammonia molecules—

and thus connecting the atoms of nitrogen.

This latter assumption is the most probable, as diammonia does not exist; and the second formula indicates that the nitrogen atoms are not directly combined with one another.

On treating Mr. Loew's formulæ for the dicarbolic isomers of amyl in a similar manner (and which obviates the necessity of assuming the existence of *di-marsh gas*—

it will be seen that they are identical with the preceding monocarbolic bodies.

In the first, the diatomic radical is—

and, as there remain five atoms of hydrogen to be divided between two atoms of carbon, two must be associated with one of the carbon atoms and three with the other.

Dicarbolic Radicals.

a. Primary.

This is identical with No. 4.

This is identical with No. 3.

b. Secondary.
Mr. Loew's.

This is identical with No. 6.

Mr. Loew's.

This is identical with No. 7.

Mr. Loew's.

Dr. Frankland's.

This is identical with No. 5.

III. Tricarboic Radicals.

By formulating these in a similar manner, we have—

Mr. Loew's.

This is identical with No. 4 and No. 9.

Mr. Loew's.

This is identical with No. 3 and No. 10.

IV. Tetracarboic Radical.

Mr. Loew's.

This is identical with No. 4, No. 9, and No. 14.

From this it will be seen that, with our present knowledge of the characters of carbon, we cannot conceive of more than eight isomers of amyl.

There is only one variety of methyl; one of ethyl, which may be viewed as methylated methyl, CH_2Me . There are two propyls:—normal propyl, which is ethylated methyl, CH_2Et , and isopropyl, or dimethylated methyl, CHMe_2 . There are four butyls:—normal butyl, or propylated methyl, containing normal propyl,

another primary butyl, containing isopropyl—

a secondary butyl, methylated ethylated methyl, CHMeEt ; and lastly, a tertiary butyl, trimethylated methyl, CMe_3 . In the eight amyls above given, we have in the four primary ones the four varieties of butyl, No. 1 containing normal butyl, No. 2 the isopropylated methyl, No. 3 contains methylated ethylated methyl, and No. 4 trimethylated methyl. Of the secondary amyls, the first, No. 5, contains methyl and propyl; the second, No. 6, methyl and isopropyl; and the third, No. 7, two of ethyl. In the tertiary amyl, No. 8, the three hydrogens of methyl are replaced by two of methyl and one of ethyl, it being dimethylated ethylated methyl.

These views will require to be very much extended if it should be distinctly shown that the four attractions of carbon differ, or, what comes to the same, that the four hydrogen atoms in marsh gas have different functions. Up to the present there are very few cases of isomerism which may not be explained by the assumption that these atoms are of equal value; there being, however, two most important exceptions in Bunsen's methylic bromide, and in the isomeric ethylic chloride obtained by acting on ethylic hydride by chlorine. If, however, the four hydrogen atoms in marsh gas have different properties, the number of isomers will be increased to a prodigious extent. By replacing one of these atoms by chlorine, four different methylic chlorides would be possible. In the next series the number of ethylic chlorides would be very much greater. The isomerism may perhaps be illustrated by numbering the

four attractions of carbon, thus, ${}^1_4\text{C}_2$; then the four methylic

chlorides will be formed by the chlorine being in the position of one of the numbers 1, 2, 3, or 4, the three remaining positions being occupied by hydrogen; there will consequently be four varieties of the radical methyl depending on the attraction which is occupied in joining the group to other radicals. Now let us imagine the molecule of methyl in the free state produced by the union of two semi-molecules,

by the attractions marked 1, we shall have ${}^4_2\text{CC}_3$. Three

ethylic chlorides are now possible according as the chlorine takes a position at 2, 3, or 4. But the carbon atoms may

be united by the attractions marked 2, the methyl ${}^4_3\text{CC}_4$ will thus be formed; this will also form 3 chlorides: the

other two possible formulæ are ${}^2_4\text{CC}_1$ and ${}^2_3\text{CC}_2$, each giving

three chlorides, or 12 in all. But we may go even farther; attraction 1 may unite with attraction 2, producing ${}^4_2\text{CC}_4$;

and in a similar manner there might be formed—

Thus we should have ten varieties of hydride of ethyl, or methyl, each capable of producing three ethylic chlorides, or a total of no less than thirty. In the propyl series the number would be vastly greater, but it will not be necessary to occupy more space in developing these isomerisms, more especially as they are perfectly hypothetical.

From the foregoing it will be seen that the lightly esteemed "theory of agglomeration and of the so-called binding and linking of the atoms," or, as it has been termed, "the interlacement of tentacles," is competent to explain almost all the isomerisms with which the chemist is already acquainted and to direct the experimenter on the track of new discoveries. The very few cases of isomerism in the methyl and ethyl series that have been clearly established would seem to indicate that there is no need to resort to such complicated explanations as those just given; but it must be remembered that if such isomers did exist their

differences would be very slight, and we may not at present have arrived at the knowledge of the means of distinguishing them. Already, in the case of two of the valeric acids, molecular weights, vapour densities, specific gravities, boiling points, and odour have failed us, and recourse must be had to the action of the bodies on polarised light in order to distinguish them from one another.

ON SOME OF THE COLOURING MATTERS OF MADDER.

By Dr. F. ROCHLEDER.

WHEN madder has been treated with mineral acids aided by heat, or, as it is technically called, has been converted into garancine, it contains, beside alizarine and purpurine, a yellow-coloured crystalline matter, which, in the underground root, is present as a glucoside. The quantity, however, of this substance is only small, and it requires thousands of pounds' weight of madder to obtain a few drachms of the mixture containing this yellow material. I received, from M. W. Brosche, a manufacturer, the raw material, which served me for the purpose of my experiments, in the shape of a brownish yellow, hard, specifically light, and readily pulverisable substance. I cannot here enter into any discussion, nor explanations, as regards the relation of the substances which I isolated from this raw material to the bodies Dr. Schunk found in his so-called rubian, and to the materials found by Dr. Schützenberger in commercial purpurine, since the analyses of the substances alluded to do not agree sufficiently mutually for this purpose. The raw material I obtained was soluble in caustic soda solution, exhibiting a blood-red colour; hydrochloric acid precipitates from this solution a bulky, gelatinous, dirty yellow-coloured flocculent matter, which, after boiling, loses its gelatinous property sufficiently to admit of collection on a filter, and of being readily washed after cooling. The solution in alkali, and the precipitation by acid, are required in order to render the material more readily acted upon by solvents. On being treated with baryta-water, the greater part of the material left on the filter is dissolved, while only a small quantity remains as a nearly black-coloured powder; the separation of these substances is effected by filtration. While I intend to say more about the blackish coloured substance hereafter, I for the present only occupy the attention of my readers with the four substances the baryta compounds of which are soluble in water. The blood-red coloured baryta-water solution is precipitated with hydrochloric acid, and the fluid containing the precipitate is heated to boiling, in order thereby to counteract the gelatinous consistency of the precipitate, which is next brought on to a filter and washed with water. The precipitate, while yet moist, was somewhat dried between folds of blotting-paper, and next heated with hydrate of acetic acid in sufficient quantity to effect a thorough solution; on cooling, this acetic acid solution solidifies, exhibiting crystalline structure. This material was placed on a filter and washed with cold acetic acid as long as the liquor running through exhibited the colour of a solution of bichromate of potassa. By this treatment, an amorphous, resinous substance, which is soluble in cold acetic acid is removed, while hardly anything else is rendered soluble. The reddish coloured solution thus obtained yields, on being diluted with water, a yellow-coloured glutinous precipitate, the quantity of which is, however, too small to make it worth while to treat it for any crystalline substances which might be contained therein. The lemon-yellow coloured mass which is left on the filter was first fractionally crystallised from a boiling mixture of acetic acid and water; next, the substances thus obtained were fractionally crys-

tallised by means of boiling alcohol; and were next, again, by means of partial solutions in alcohol and water, separated into various compounds. It would lead too far to explain here the applications of ammonia, carbonates and bicarbonates, chloride of iron, &c., used by me for the purpose of separating the substances. The four bodies which I have isolated from each other are, as regards their behaviour with solvents, so nearly related to each other, that their separation can only be effected by frequently repeated and tedious operations; and, as regards their properties, too, they are so akin to each other that only by a series of analyses I could find out whether they required more purification. I only obtained small quantities of the pure substances, and hence it was impossible so fully to investigate their relations as to deduct therefrom results in respect of their constitution. The product present in the mixture to the largest extent, after the removal of the resinous body alluded to, is isalazarine, because it has the same composition as alizarine, from which it is, however, distinguished by its blood-red colour when in solution in aqueous solutions of caustic soda and potassa, and by its red colour when dissolved in baryta water. The colour of this substance holds the middle between those of alizarine and purpurine. It does not dye cotton previously mordanted with iron or alumina mordants; it cannot be obtained in large crystals. The four following analyses refer to materials obtained by a different mode of preparation:—

Calculated.		Found.			
		I.	II.	III.	IV.
C ₁₄ =	168	70'18	70'02	70'03	70'01
H ₈ =	8	3'61	3'62	3'65	3'61
O ₄ =	64	26'21	26'36	6'32	26'38
			2		
	240	100'00			

Isalazarine is accompanied by a second material present in the raw material, in so extremely small quantity that I could only just manage to make one analysis, which led to the formula C₁₅H₁₀O₄. This material may be readily confused with isalazarine, and its presence in that substance explains the somewhat too high proportion of H found in isalazarine. A third companion of isalazarine is hydrisalazarine; its colour is rather more bright yellow than that of isalazarine. It (hydrisalazarine) is soluble in a boiling solution of perchloride of iron, with a dark brown colour; it partly precipitates on cooling, partly on addition of a few drops of hydrochloric acid, in the shape of a bright yellow-coloured flocculent matter; it is not at all changed or altered in any way by its solution in the chloride. Four analyses led to the formula C₁₈H₁₈O₈. When alizarine is written—

hydrisalazarine is expressed by—

The fourth companion of isalazarine and the two other substances alluded to is homologous with hydrisalazarine, according to the formula C₂₀H₂₀O₈. When this substance is kept for some time at from 118° to 120°, it loses OH₂, thereby assuming a more dark colour. I take this opportunity of calling attention to the composition of ruberythrinic acid, found by me now many years ago in madder; its composition is correctly expressed by C₂₀H₂₂O₁₁. By the action of acids, this substance, as was then pointed

out by me, is converted into alizarine and sugar, according to the following formula:—

ON FERMENTATION.*

By Professor A. W. WILLIAMSON F.R.S.

LECTURE I.

I HAVE sometimes wished, when building castles in the air, that I could, after a few hundred years, come back and see the state of science at that time. I am convinced that those who will look back, from such a period as a few hundred years hence, at the present state of our knowledge of nature in any one department will be surprised at its smallness; in fact, even now, when we work at all earnestly at any one part of the field of nature, we cannot refrain from feeling how little is our knowledge compared with our ignorance. But, if that is generally the case, I think it is peculiarly the case in those studies in which life is concerned, and the phenomena of fermentation have that peculiarity that they consist in processes in which vital organisms are concerned, and in which there is every reason to believe that vital organisms, or living beings, take an active and leading part. I need not say that, for that reason, the explanations which we have, even of the simplest and best known of the phenomena of fermentation, are, as yet, mere sketches of the reality. It is, however, not the less useful or the less important to know them for that reason.

When we chemists are classifying substances, we adopt a principle of classification which I think is almost inevitable, but it may be as well that I should mention what it is. We put the simple things together, and the complex or difficult things together, and then we try to put between them, in as regular an order as possible, the intermediate links of the chain by which they can be connected; and I believe that our best—I might almost say our only—explanations consist in thus arranging, in a natural order, the facts which we have to consider, and then viewing them, and stating what we see, in the clearest and least ambiguous terms. Now, the term "organic," as applied to a certain class of chemical substances, might be replaced—and I think, for some purposes, ought to be replaced—by the term "complex." The substances which we are in the habit of including under the term organic are peculiarly complex; in fact, they are the most complex with which we have to do. The phenomena of fermentation relate mainly to them, and consist principally of a process of change—the breaking-up of those organic bodies into rather less complex substances than themselves—a process of partial analysis. Of course, when I say that, I give what I conceive to be a characteristic idea of the general method, and I must not be supposed to assert that all processes of fermentation are analytical.

Amongst the characteristics which I think are particularly useful and interesting, as serving to distinguish organic from inorganic, complex from simple substances, is their different behaviour under heat. I have found it exceedingly interesting and instructive to bear in mind the fact that, while simple and inorganic compounds, as we generally call them, are sometimes destroyed and resolved into other compounds by the action of a high temperature, yet many of them are not. Amongst inorganic substances we find some which are broken up or changed by exposure to a high temperature, but there are others which can stand even the highest temperature without undergoing any permanent change; that is to say, they return, on cooling, to the same state in which they were before the heat was applied. With organic substances that is not the

* The Cantor Lectures. Delivered before the Society of Arts.

case. All organic bodies are broken up into minute particles, and assume new arrangements, when they are heated to a sufficiently high temperature; and that is, I think, a distinction which is of considerable theoretical, as well as, perhaps, of some practical, importance.

The processes of breaking up which are effected by heat upon organic bodies are, in the very great majority of cases, different from those which are effected by the action of these wonderful little organisms, the ferments; and it is a peculiarity of the action of the ferments that they effect the breaking up—the analysis—of complex organic substances, and form products which, for the most part, we have obtained from those materials by no other process.

Amongst the processes of fermentation, there is one which, from its pre-eminent importance, and from the fact that we have had occasion to study it more fully than any other, ought to be first mentioned. I allude to the process of fermentation by which alcohol is formed artificially. I may say, indeed, it is the only process by which alcohol is ever made. It is a process which consists in breaking up some kind of sugar, for sugar is a word which, although popularly restricted to one particular substance which is extracted sometimes from the sugar-cane and sometimes from beet-root, is used by chemists in a more general sense, serving to characterise a family of bodies which have much in common with one another, being for the most part all of them sweet, and containing the same elements, but in slightly different proportions. They all possess many properties which are of some importance. These different kinds of sugar are broken up by the action of ferment into alcohol, and also into another product, carbonic acid gas, which has been long known, and for a long time the process of alcoholic fermentation was supposed to consist simply in a separation of sugar into these two products, alcohol on the one hand and carbonic acid on the other. A more careful examination of the products has shown, however, that these two never appear alone. I believe I may safely say, from the researches of Pasteur and others, that no case of the formation of alcohol by fermentation has been known to occur in which several other products have not been formed simultaneously with these two. With regard to the difference of properties of these two bodies, there are one or two points of some little interest, especially this one, that whereas alcohol is an eminently combustible substance, and is well known to have properties of that kind, being frequently used as fuel, on the other hand, carbonic acid, the other chief product, is completely burnt—it is a substance incapable of undergoing any chemical change whatever analogous to combustion. Alcohol is a substance which I need not show you, although in its pure state it is not very common, but I will, in order to remind those of you who may be less familiar with its leading properties, make a little carbonic acid by a short process. I will put a little muriatic acid upon some white marble, and the apparent ebullition which you see takes place is known to you all as due to the liberation of carbonic acid. You might imagine the thing to be fermenting, only that the process in that case would be less rapid. Now, if I plunge this little burning paper gradually into the jar containing the carbonic acid, it will burn more and more faintly, and get extinguished when it enters the gas; it is totally impossible to set fire to the gas. And there is one other fact that we may notice at the same time—the great specific gravity which characterises this gas. I will show you that, in this way. I will go through the motion of pouring from this jar containing it into another smaller jar; and no doubt the heavy carbonic acid will pass from the jar in which I first collected it into the lower one, where we shall find it by means of the taper as before. You see that, on lowering the lighted taper into this small jar, it is extinguished as it was before. I will show you the test by which we usually discover the presence of carbonic acid. I have here some water containing lime in solution—some lime-water—and I will pour it into the large beaker-glass, in which there is probably still some carbonic acid left. You see the solu-

tion immediately becomes turbid, or, as we express it, a precipitate is formed by the combination of the carbonic acid with the lime-water. A compound is formed, which is nearly insoluble in the water, called carbonate, which goes down as a precipitate.

In addition to alcohol and carbonic acid, I ought to mention another kind of alcohol, which occurs to a considerable extent in some distilleries where raw grain or potato-starch is used. This substance imparts to the product a very unpleasant odour, and some unwholesome qualities. It is known by the name of fousel oil. It does not mix with water; and if I were to pour some of it on water, it would float, without dissolving to any considerable extent. There are some other products which are even more interesting and important; two especially I ought to mention. One is the clear substance which you see in this bottle, and which you might imagine to be oil; it is a fluid largely made now, and known by the name of glycerine, but in chemical language I should say that this was an alcohol. It is a substance which, by tasting, you might mistake for sugar, for it possesses a sweet taste, resembling sugar; but, to chemists, it is a kind of alcohol, and its appearance during fermentation together with ordinary alcohol is no doubt due to a process of the normal kind.

Another product which I might compare to the carbonic acid which I just now showed to you, is this beautiful crystalline acid substance, which has long been known by the name of succinic acid. It got that name from the fact that it was originally prepared from amber. By subjecting the amber to dry distillation, succinic acid, among other products, is formed. Glycerine and succinic acid, as well as common alcohol and carbonic acid, are always formed when any kind of sugar is made to decompose by the process which is termed alcoholic fermentation, and it is seldom that there are not other—and probably, in smaller quantities, several other—products formed besides those four. In fact, the different kinds of spirit which are obtained by the process of fermentation, and subsequent distillation—I mean those kinds of spirit to which no artificial flavouring is added (gin is a general name given to certain spirits which are flavoured by artificial means), such as brandy, rum, and others—owe their distinctive peculiarities to the presence of small quantities of volatile substances which are formed during the process of fermentation, regarding which a good deal has been observed, and several important facts have been collected.

There is another process of fermentation which I must mention, for it is important from its frequent occurrence, and that is a process by which another kind of sugar usually, but sometimes common sugar, is transformed. The substance which most naturally undergoes this fermentation is milk-sugar. These hard lumps in this bottle, which, if you were to take out and taste, you would not imagine to be sugar, are made by the crystallisation of the solid substance in whey. The whey is evaporated carefully to a small bulk, and this substance which results is known by the name of milk-sugar. When a solution of this is mixed with cheese, which is the best ferment for the purpose, it gradually turns acid. I dare say it is known to all of you that milk itself, which contains this body, and cheese, or rather casein dissolved with it, together with the fatty globules of milk, when exposed to the air, turns acid. That acidity is due to a change which takes place in the sugar. The sugar disappears gradually, and is transformed into an acid substance, of which I have a little bottle here. It is a strong acid; and here, in another bottle, are a few of its salts—a lime salt and a zinc salt, which is a very beautiful and characteristic compound. I shall have occasion hereafter to show you a large bottle which is now at work, in which I dissolved, not this particular kind of sugar, but the ordinary sugar. I put with it a quantity of calcic carbonate, and some old lean cheese, with a considerable quantity of water. The mixture was kept at a temperature above blood heat for some considerable time, and a compound of lactic acid is being formed. That is a process analogous in its general features to the fermentation

which forms alcohol, but it is a change of sugar in which no alcohol is formed. Sometimes there is a trace of alcohol, but there is not necessarily any, and no carbonic acid is formed; but, instead of those products, the elements of the sugar break up into different groups and arrange themselves in another manner. That is really the nature of the process, as far as our most careful experiments have gone; and the acid which we make in that way, which is lactic acid, or acid of milk, is really sugar, of which the elements are arranged in a different way, so as to acquire acid properties.

The third process, which I must mention from its remarkable products, is one which, perhaps, in some respects, ought rather to be compared with putrefaction, for it is a process which has many of the most important characteristics of putrefaction. In order to deal with the question of fermentation generally, it is necessary to allude to some varieties of such chemical changes which are usually classed under the term putrefaction. As a general rule, I think the characteristic of processes of putrefaction is mainly the unpleasant nature of the products which are formed. It is not long since a distinguished chemist, in speaking of alcoholic fermentation, said that it is really a putrefactive process; and in its intimate nature it is, as far as we know, a process much like the truly putrefactive processes, and different from the processes of *fermentation* or oxidation. This other process to which I allude consists in forming the acid substance which I have here, and which I will not open, because it is not a very pleasant body; it is a substance which is known, although I believe not very commonly, in butter. The peculiar rancid odour which butter acquires when it is kept too long, especially in warm weather, is due to a transformation of some of its materials into this particular acid, which Chevreul, a very distinguished French chemist, separated from butter, and he named it, from that circumstance, butyric acid. If we leave some of this product of the last fermentation—some of this lactate of lime, the lime-salt of lactic acid—under the same conditions in which it was formed, that is, if we leave it in the same vessel in which it had been formed from the milk or sugar, and leave cheese with it, and keep the mixture warm, the lactate will gradually decompose, and carbonic acid will be given off together with hydrogen gas; and, at the same time, we find that the lactic acid will be decomposed, and in place of it we get this butyric acid, and generally some valerianic acid and a little acetic acid.

(To be continued.)

ON THE ESTIMATION OF MANGANESE.

By Dr. MOHR.

SOME discrepancies in the results of analysis of manganese, especially that imported from Spain, have been noticed, according as the method of analysis (quantitative estimation of peroxide of manganese) employed was that of Fresenius and Will, or that known as the iron test. The cause of this discrepancy has been found to be due to a larger or smaller amount of magnetic oxide of iron present in and along with the manganese ore. When the method of Fresenius and Will is applied to the estimation of manganese this admixture of oxide of iron is quite indifferent, because neither of the oxides of that metal exert any action upon oxalic acid; but when the so-called iron test is applied for the purpose alluded to, the protoxide of the magnetic iron ore is converted into chloride, and there remains, therefore, a correspondingly larger quantity of the double salt of iron which has been added. Since the same reaction occurs when such a manganese is applied for the manufacture of chlorine, and since the quantity of the latter gas set free is only that which remains after the oxidation of the magnetic iron ore, the manufacturer who purchases such manganese is entitled to pay for that

article only its value as peroxide of manganese. It, however, frequently occurs that the mining and manufacturing interests here clash, and that, as a consequence, the ore proprietor will desire the value of his material to be estimated by the method of Fresenius and Will, while the manufacturer prefers that of the iron test. That right as well as equity are on the manufacturer's side is clear from the following instance:—Suppose a mixture of one atom peroxide of manganese, (MnO_2), and two atoms magnetic iron ore, $2(Fe_3O_4)$, or 27.3 per cent of the former along with 72.7 per cent of the latter; in such a mixture the method of Fresenius and Will will indicate with precision the amount of peroxide of manganese, but on adding hydrochloric acid to this mixture not a trace even of chlorine will be given off, since the free atom of oxygen of the peroxide of manganese is just sufficient for the oxidation of the two atoms of protoxide of iron of the magnetic iron ore; in the same way a mixture of manganese with protosulphate of iron or protocarbonate of that metal will be perfectly worthless as an article for the chlorine-making use.

The author recommends that manganese ores and samples of peroxide of manganese should be always tested, previous to analysis, with an astatic magnetic needle, and he further recommends as the best and surest method of analysis of peroxide of manganese, the following:—Distillation of the ore with hydrochloric acid, collection of the chlorine gas given off in an aqueous solution of iodide of potassium, and estimation of the iodine set free by means of a 1-10th solution of hyposulphite of soda; this process is really the same as that which the manufacturer employs for making chlorine; any magnetic iron ore present will become oxidised in both these processes (the testing just described and the chlorine making on the large scale), and an examination for magnetic oxide of iron is rendered unnecessary, while the available manganese for the production of chlorine only is estimated.—*Zeitschrift für Analyt. Chem.*

ON THE ABSORPTIVE PROPERTIES OF SILICA, AND ITS DIRECT HYDRATION BY CONTACT WITH WATER.

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

IN No. 157 of the *CHEMICAL NEWS*, I communicated the fact that silica is hydrated and dissolved by aqueous solution of ammonia. Evidence in favour of this being given in a recent number of the same journal, together with particulars as to the amount of this solubility, I thought it desirable to ascertain whether ammonia is absolutely necessary to ensure this, the first of these reactions, the hydration of the silica; it occurred to me that water might effect it of itself—the action of ammonia, in this instance, being confined to bringing the silica, thus hydrated, into solution.

The following experiments tend to show this assumption to be correct:—

Rock-crystal, finely pulverised in an agate mortar, then agitated with water, did not completely subside, even after the lapse of some days; the water remained turbid, like clay-water, and, like it, is soon clarified by the addition of an acid or a neutral salt.

The effects of such additions would, I conceive, rather retard the precipitation of the silica, by increasing the gravity of the fluid, were it not that combination between the silica and the water had commenced—were it not, also, for an affinity of this substance for water under these conditions—feeble, no doubt, as to intensity, but insatiable as to quantity.

There appears to be one weak point in the evidence here tendered—viz., that agate (the substance of the mor-

tar used) is not pure silica; still, it is so nearly pure, that, upon the whole, it is, I think, quite safe to leave this matter out of further consideration.

In reference to other absorptive properties of silica, I find that massive quartz, rock-crystal, and silica, prepared for estimation in the usual way, take sesquioxide of iron from solution of its acetate, but not from the chloride.

Prepared silica, especially, manifests this property, if ignited at a low temperature; and, besides, takes oxides of chromium and copper from their acetates, and removes certain organic matters from their aqueous solutions. These reactions are more apparent in this case, because the silica is in a finely divided state, *chemically* pulverised in fact.

These reactions show silica to be a feeble mordant, and I think they have an intimate relation to what is termed the physico-mechanical absorption of soils, &c., since we thus see that one of the main constituents of rocks and soils, supposed to be at once the most inert and the most insoluble in an ordinary way, are capable of chemically absorbing certain substances to an extent proportionate to that of the surfaces exposed; such surfaces, even those of rock-crystal itself, are certain to be in a hydrous, in fact in a pulpy state, whenever water has had prolonged contact with them. It follows, therefore, if a substance, which has hitherto been held to be so inert and so unassailable, in these respects, as quartz, is thus actually affected in this manner, we may be certain that the great bulk of our soils, and our more porous rocks, have been affected by water and saline substances in a similar manner;—we may be quite certain that the surfaces of every siliceous stone, and of every grain of siliceous sand in our soils, is hydrated, and, by so far, advanced to the possession of what is termed the physico-mechanical absorptive power for plant-food.

It only remains for me to state that the reactions here described tend to resolve the so-called "*physico-mechanical* absorption of soils for plant food," into a simply chemical one, or at least, as much a chemical one as are any of those undisputably recognised as such.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 3rd, 1870.

Professor WILLIAMSON, F.R.S., President, in the Chair.

The following gentlemen were elected Fellows:—
D. Howard, J. Muter, C. W. Siemens, F.R.S.

On opening this first meeting in the new session, the President alluded, in a few earnest words, to the loss the Society had recently sustained through the death of two of the most distinguished of its members.

The following papers were read:—

"On the Production of the Sulphates of the Alcohol Radicles from the Nitrates by the Action of Sulphurous Acid," by E. T. CHAPMAN.

When sulphurous acid gas is passed into nitrate of amyl it is rapidly absorbed. The nitrate changes in colour from yellow to green, from green to blue; it then begins to effervesce, and at the same time becomes hot and boils violently. Nitric oxide is evolved in abundance, and a yellow liquid product remains. This liquid cannot be distilled without decomposition. It contains no nitrogen. When an attempt is made to distil it along with water, the oily liquid found in the distillate consists principally of amyl alcohol. When the liquid is distilled *per se*, it blackens, gives off sulphurous acid, and yields a complex distillate, which contains, amongst other things, valerianate

of amyl. This circumstance stood in the way of any attempt to obtain an insight into the nature of this reaction. Mr. Chapman resolved, therefore, to attack the question quantitatively. With this object, he determined the nature and amount of the gas evolved, by the action of excess of sulphurous acid on a known weight of the nitrate. The result proved that the gas evolved consisted of pure nitric oxide, and that the whole of the nitrogen present in the nitrite escaped in this form. The amount of sulphurous acid necessary to decompose a given quantity of nitrite, was also determined by observing the quantity of sulphurous acid which disappeared when an excess of sulphurous acid acted on a known quantity of nitrite. It was thus ascertained with sufficient accuracy that one atom of sulphurous acid acted upon two atoms of nitrite of amyl, and liberated two atoms of nitric oxide. Lastly, the alteration of weight which nitrite of amyl undergoes by the reaction was determined. The result confirmed the supposition that the reaction consisted in the replacement of two atoms of nitric oxide by one of sulphurous acid.

The resulting liquid compound had, therefore, the composition of neutral sulphate of amyl. It readily breaks up into amyl alcohol and sulphuric acid by boiling with water, and by long standing even with cold water; treated with strong hydriodic acid it yields sulphuretted hydrogen, water, iodine, and amyl iodide; potassic bichromate and sulphuric acid cause it to yield valeric acid. It is to be observed that it is necessary gently to warm the retort in which the nitrite is exposed to the action of a stream of dry sulphurous acid; if this is not done, the SO_2 is absorbed for some time without any reaction occurring, but when the reaction does start it is with almost explosive violence, whereas if gentle heating has been applied from the beginning the reaction starts at once and goes on regularly. It is also desirable to pass through the apparatus carbonic acid or hydrogen, before the SO_2 has been passed into the nitrite, and to do this also afterwards for the purpose of excluding air, the oxygen of which would unite with the NO, and the SO_2 would then be expelled.

Sulphurous acid and butylic nitrate react upon one another in a manner analogous to that of SO_2 or amyl nitrite, but the resulting product is even more unstable.

Sulphurous acid and nitrite of ethyl do not readily act upon each other, at least not at the common temperature.

Mr. Chapman then proceeded to the theoretical considerations which are suggested by the above facts. Are these compounds properly speaking sulphates of alcohol radicles, or only isomeric bodies with them? The reaction of the amyl compound with water is very different from that of sulphate of ethyl under similar circumstances; it does not, when boiled with water, form an acid analogous to isethionic acid, but splits up into sulphuric acid and amyl alcohol. This would suggest a different linking of the molecules; most probably in the common amyl sulphate the two organic radicles are linked to oxygen directly, and by oxygen to sulphur; in the amyl compound obtained from the nitrite one of the radicles is attached directly to sulphur, and the other indirectly through the oxygen.

Mr. Chapman then described the apparatus by which the nature of the reaction of sulphurous acid on amyl nitrite has been determined. The evolved nitric oxide was transformed into nitric acid and this treated with barytic carbonate.

In the discussion following this paper, Dr. Debus and Mr. Harcourt expressed their apprehension that along with the barytic nitrate also some barytic nitrite may have been formed. Mr. Chapman replied that he had taken great care to ensure the complete transformation into nitric acid; that to this end he had passed great quantities of oxygen into the collecting cylinder, left the mixture standing for twenty-four hours over the water in

MISCELLANEOUS.

retard the ^{of} London.—The following are lists of the gravity of ^{who} have passed the second B.Sc. examination the silica ^{at} *Division*.—John Ambrose Fleming, University for an affinity Thomas Hick, B.A., private study. *Second* conditions—feeward Bibbins Aveling, University College; to quantity_s, College of Chemistry and private study; There armer Thistleton Dyer, private study; John here tende artley, B.A., University College and private

study; Henry Newell Martin, First M.B., Christ's College, Cambridge, and University College, London; Thomas Firth Moorhouse, private study; Robert Davies Roberts, University College; Robert Routledge, Owen's College; Frank Salter, University College.

Phosphate of Lime as a Mordant.—Dr. Reimann.—A rather thick syrupy solution of phosphate of lime (bone-ash) in hydrochloric acid having been recently recommended as a mordant to be used after a previous sumacking of the goods, the author states that, according to his researches, the phosphate of lime solution is altogether superfluous, since a sumacking with 4 lbs. of sumac to 20 lbs. of cotton is of itself a sufficient mordanting to fix aniline colours excellently. The application of the phosphate of lime solution as a mordant for cochineal colours upon cotton the author also considers as quite useless.

Solution of Water Glass.—Dr. Flückiger.—This solution is precipitated by a solution of nitrate of soda, and the following curious phenomenon is exhibited; when a solution of silicate of soda of 1.392 sp. gr. is precipitated with a solution of one part of nitrate of soda in one of water the silica is immediately separated, but if the nitrate is dissolved into two parts of water, and if equal parts of both liquids are mixed, no precipitate ensues until the mixture is heated to 54°, when silica separates in a gelatinous state so as to cause nearly the solidification of the mass. If this experiment is made in a small flask and the vessel suddenly cooled again, either to the ordinary temperature or even below 0°, the silica is suddenly dissolved again; this experiment may be repeated any number of times.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgement. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Sitzungsberichte der Königlich Bayerische Akademie der Wissenschaften zu München, Vol. i., No. 1, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and allied sciences:—

Comparator for the Indication of the Toise and the Meter, and also for the Determination of the Absolute Longitudinal Expansion of Rods.—Dr. von Steinheil.—This paper, illustrated by engravings, contains the description of an instrument (comparator) devised by the author for detecting the absolute longitudinal expansion of metallic rods employed for the construction of measures of length.

Changes which the Colours of some Blossoms and Flowers Undergo when Exposed to Ammonia Gas.—Dr. Vogel.—The author relates, at great length, a series of experiments extended over no less than eighty-six species and varieties of flowers, and made with the view to learn how the colours thereof are affected by the action of ammonia gas, the flowers being exposed to that gas by being placed under a bell-jar filled with the gas, and left in that condition for from a quarter of an hour to two, or even twelve, hours. Among the general results obtained by the author, we notice that he found marked difference to exist between the action of the gas upon flowers, the colouring matter of which is fixed in small granules, and that which is present in solution; the former is far less changed than the latter. Among the eighty-six kinds submitted to research, twelve exhibited no change whatever; of these, seven were yellow, and five deep violet-coloured. Deep violet-coloured flowers are not at all affected, and some blue colours also stand the action of the gas for a time very well. The alteration produced by the gas is, in most cases, very akin to that called forth by the fading away of the flowers. The yellow colouring matter of the *Lotus corniculatus* exhibits a great stability, since it withstands the action of ammonia gas for twelve hours without change. On becoming dry, this colouring matter becomes bright green.

Quantity of Water Evaporated by an Oak-Tree during the entire period of its Growth.—F. Pfaff.—This lengthy treatise con-

tains the results of photo-physiological experiments made with the view to ascertain the quantity of water evaporated during the entire period of vegetation of an oak-tree, as deduced from very minutely and accurately executed experiments, and in order to illustrate the effects of trees and forests as affecting the rainfall. The essay is accompanied by lengthy tabulated forms containing a series of figures.

On Rabbionite, a New Mineral Species, and on an Asbolan which contains Lithia.—F. von Kobell.—Rabbionite is a mineral exhibiting a dull black colour; it becomes metallic-like when rubbed; is very soft; its powder is deep brown-coloured. The sp. gr. of the mineral is 2.80; it fuses in the blowpipe flame, yielding a steel-blue coloured globule which acts upon the magnetic needle (the mineral does not do so before being fused). On being heated in a small flask or test-tube, water is given off. The mineral is readily soluble in hydrochloric acid, chlorine being evolved, but hardly soluble in nitric acid. Analysis, in 100 parts, gave—Peroxide of iron, 45.00; peroxide of manganese, 13.00; alumina, 1.40; oxide of copper, 14.00; protoxide of manganese, 7.61; oxide of cobalt, 5.10; water, 13.5;—total, 99.61. The name rabbionite is derived from the greek word *rabbion*, a small rod, because the mineral occurs in a shape resembling this. The mineral was obtained from the Nischne-Tagilsk mines, on the Ural (Russia). The author briefly mentions some researches instituted by him with a mineral which was stated to be asbolan, but differs in composition from a mineral of the same name analysed by Dr. Rammelsberg, inasmuch as the mineral investigated by the author contained lithia in very small quantity, however, and, besides, 54 per cent of peroxide of manganese, 4 of oxide of cobalt, 0.61 of oxide of copper, 13.4 of water, and 23 per cent of alumina.

Vol. I., No. 2, 1870.

This number contains the following original papers and memoirs relating to physico-chemical sciences:—

Researches on Electrical Discharge.—Dr. W. von Bezold.—This paper has been given in an enlarged and more complete form in another periodical, from which we have briefly abstracted it (see CHEMICAL NEWS, vol. xxii., p. 227).

On the Riesvulkan, and on Volcanic Phenomena in the Ries-kessel.—Prof. Gümbel.—This lengthy memoir contains the detailed account of a geognostic and mineralogical investigation of a mountain belonging to the Swabian Jura chain.

Vol. i., No. 3, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

On Lüneburgite.—C. Nöllner.—The author states that, a boring having been made with the view to reach deposits of salt in the neighbourhood of Harburg (Prussia), a new mineral was found, to which the name lüneburgite was given. The composition of that mineral, in 100 parts, is—Magnesia, 16.75; water, 3.78; phosphoric acid, 29.83—this portion forming a separate salt, but combined in nature with the following constituents:—Magnesia, 8.35; boric acid, 14.72; water, 26.17. Formula of lüneburgite—

On Gümbellite.—Dr. von Kobell.—The substance alluded to is a new mineral, named after its discoverer, M. Gümbel. The mineral occurs in thin layers on thonschiefer. The colour is whitish green; melts before blowpipe-flame with some difficulty, forming a porcelain-like mass. Heated in a flask or test-tube, water is given off; insoluble in hydrochloric and sulphuric acids. It consists, in 100 parts, of—Silica, 50.32; alumina, 31.04; peroxide of iron, 3.00; magnesia, 1.88; potassa, 3.18; water, 7.00; matter undecomposable by fluorhydric acid, 1.46;—total, 98.08.

Vol. I., No. 4, 1870.

The following original papers relating to chemistry and collateral sciences are found in this number:—

Luminosity of the Water Hammer.—Prof. Lommel.—This memoir contains the account of a series of experiments made with the view to ascertain whether the instrument known as the water hammer (in this instance constructed of glass tubes of from 15 to 23 centimetres' length, by from 10 to 15 millimetres' width, and provided on one end with a bulb of about 4 centimetres' diameter, the tube being partly filled with pure water freed from air by long-continued boiling) would, when electrified as Geissler's tubes, produce phenomena similar to the latter when electrified. The author found that the water hammer acts in a very similar manner as do the Leyden jars, which are connected with the conductors of electric machines (*influenzmaschine*) for the purpose of obtaining stronger sparks; moreover, the tubes alluded to exhibited brilliant luminous phenomena.

Vol. II., No. 1, 1870.

This number contains the following papers relating to physico-chemical sciences:—

Crystal Water.—Dr. F. von Kobell.—This very lengthy treatise sets forth the following facts:—Water of crystallisation is an absolute requisite necessary to the very existence of a chemical species. This water therefore belongs to the true chemical constitution of a body, and is not an appendix to its physical properties, as is the case with hygroscopic water. When the water necessary for the existence of any compound is termed water of constitution, all water of crystallisation has to be so named, because it is absolutely necessary to form the specific compound, which is altered and changed in its character as soon as the water is eliminated.

Annalen der Physik und Chemie, von Poggendorff, No. 9, 1870.

This number contains the following original papers:—

Calorimetric Researches.—R. Bunsen.—This lengthy memoir, illustrated by engravings, is divided into the following sections:—The ice calorimeter; estimation of specific heats. The contents of this memoir more strictly belong to the domain of algebraical than experimental natural philosophy. The paper abounds with formulae and tabulated results.

Relation Existing between the Crystalline Form of Bodies and the Chemical Constitution of some Organic Compounds.—P. Groth.—The author states that his object in writing this paper has chiefly been the investigation of the relation which exists between the crystalline form of a chemical compound, and the change that form undergoes when, for one or more of the hydrogen atoms of the compound, are substituted other groups of atoms. The author illustrates this by several instances—as, for instance, benzol, C_6H_6 , which crystallises in the rhombic shape, while its first hydroxyl-derivative, phenol, assumes the same shape. The contents of the paper are, however, purely crystallographical, and, therefore, not suited for further abstraction.

Experimental and Theoretical Researches on the Equilibrium Figures Exhibited by a Fluid Mass not endowed with Gravity.—J. Plateau.—Eighth paper on this subject.

Absorption of Light.—P. Giam.—A mathematico-physical essay illustrated with engravings.

Appendix to a Paper on "Researches concerning the Behaviour of Vapours as regards the Laws of Mariotte and Gay Lussac."—Dr. H. Herwig.—This paper is chiefly a collection of tabulated results of experiments.

Analogy Existing between some of the Principal Axioms of Photometry and the Doctrine of Attraction.—W. Bezold.—An algebraical essay.

Luminosity of Phosphorus.—W. Müller.—The contents of this paper are an extended report of the author's experiments on this subject, already quoted, in its essential details, from another periodical (see CHEMICAL NEWS, vol. xxi., p. 199).

Peroxides of Metals which can be Obtained by Electrolysis.—W. Wernicke.—This lengthy essay treats on lead, manganese, bismuth, cobalt, and nickel. The author's results of experiments may be summarised as follows:—The peroxides of metals separated from alkaline or neutral solutions by means of electrolysis are hydrates, composed according to the formulae $RO_2 \cdot H_2O$ or $R_2O_5 \cdot 2H_2O$. The composition and specific gravity of the substances investigated are:—Hydrated peroxide of lead, $PbO_2 \cdot H_2O = 2.57$; hydrated peroxide of manganese, $MnO_2 \cdot H_2O = 3.51-2.56$; hydrated peroxide of bismuth, $BiO_2 \cdot H_2O = 5.574$; hydrated peroxide of cobalt, $Co_2O_3 \cdot 2H_2O = 2.483$; hydrated peroxide of nickel, $Ni_2O_3 \cdot 2H_2O = 2.744$. These substances exhibit, in thin layers, most magnificent interference colours, and, for the technical purposes of metals—chromy, the colours exhibited by the hydrated peroxide of cobalt will be valuable, on account of being readily prepared and permanent. The compounds alluded to were only produced by very weak electric currents; stronger currents produce other compounds containing less oxygen.

Mechanical Law Applicable to Calorics.—R. Clausius.—An algebraical essay.

Spectra Exhibited by Negative Electrodes and by Geissler Tubes which have been Used for a Long Period of Time.—Dr. E. Reitlinger and M. Kuhn.—An extensive and concisely-written essay, not suited for any useful abstraction.

Changes Produced in the Brown Coal (Lignite) of the Meissner by Coming into Contact with Basalt.—Dr. A. von Lasaux.—The locality designated as the Meissner is a mountain situated in the Prussian province of Hessen. The paper is chiefly written with the view to prove that the changes which the lignite has undergone by coming into contact with basalt does not prove the igneous origin of the latter. The paper contains several analyses, among which are the following (all substances dried at 100°): Anthracite (sp. gr. 1.412).—In 100 parts: Carbon, 80.40; hydrogen, 3.30; sulphur, oxygen, and nitrogen, together, 5.67; bituminous matter, 0.73; ash, 9.90;—total, 100.0. A material named *stangen kohle*, that is, a coaly matter in the shape of rods (sp. gr. 1.207).—In 100 parts: Carbon, 78.14; hydrogen, 3.75; sulphur, oxygen, and nitrogen, together, 4.03; bituminous matter, 0.85; ash, 13.17;—total, 100.0. Deep black-coloured coaly matter (sp. gr. 1.280).—In 100 parts: Carbon, 62.20; hydrogen, 5.28; sulphur, oxygen, and nitrogen, together, 22.75; ash, 9.77;—total, 100.0. Bituminous matter in this coal was 15 per cent, and it was found to be partly soluble in caustic potassa, which is not the case with the other two samples. Compact brownish black-coloured lignite (sp. gr. 1.251).—In 100 parts: Carbon, 59.92; hydrogen, 5.66; sulphur, nitrogen, and oxygen, 26.12; ash, 8.30;—total, 100.0 (contains a large proportion of bituminous matter, and is in a great measure soluble in caustic potassa solution). In order to investigate the effect which a fused mass, as basalt has sometimes been supposed to be, would have upon this lignite, a considerable quantity was exposed to the action of molten blast-furnace slags, and the pieces so exposed analysed, the result being (sp. gr. 1.361, in 100 parts): Carbon, 80.36; hydrogen, 3.04; sulphur, nitrogen, and oxygen, 1.20; ash, 15.40. The lignite was exposed to the action of the slags in fire-clay crucibles and under a cover of fire-clay.

Analysis of Silicates.—E. Ludwig.—This paper treats on the analysis of a felspar from Narddal (Norway), which, having been analysed by the author, as well as by Dr. G. von Rath and Professor C. Kammelsberg, yielded, to each, results which exhibit rather great discrepancies in the quantity of silica and alumina obtained by these authors, varying, for silica, from 51.78 to 48.94 per cent, and for alumina

from 33.36 to 30.77 per cent. The author's paper is a lengthy essay on the different methods in use for estimating silica and alumina when present in complex minerals, but, unfortunately, the bulk of the essay consists of quotations of results of test analyses, and is, therefore, not well suited for farther quotation.

Absorption-Spectrum of Fluid Hyponitric Acid.—A. Kundt. Observations on Dr. Boltzmann's Paper "On the Force Exerted by Moving Masses of a Gas."—Dr. Kurz.

Politechnisches Journal von Dingler, first number for October, 1870.

This number contains the following original papers relating to chemistry and allied sciences:—

The Tallow-Melting Industry.—Dr. H. Vohl.—This paper, illustrated by engravings, treats on the best methods to prevent the complaints, often, and not unreasonably, made, about the smell and nuisance arising from the melting of tallow. The author describes at length a contrivance whereby the melting of tallow may be conducted without giving rise to any complaints. Unless we were to reproduce the engraving, absolutely required to understand the arrangement, we could not enter into further details on this subject.

Description of the Adalbert Ironworks at Kladno (Bohemia).—J. Zeman.—This paper, illustrated by several engravings, is the first portion of a detailed description of an ironwork which, however interesting it may be for the Continent, is surpassed, in extent and perfection of arrangement, by several similar works in the United Kingdom.

Desilvering Lead by means of Zinc.—C. M. Balling.—A lengthy treatise, illustrated by several engravings, containing a detailed account of the process alluded to as practically executed in different countries.

NOTES AND QUERIES.

Estimating Tartaric and Citric Acids.—(Reply to A. J. M. Edger).—You will find the information you require, too lengthy to be here printed, in Richardson and Watts's "Chemical Technology," vol. i., part 5, pp. 198 and following and 178 and following.

Manufacture of Anthracene.—I have been requested to enquire whether there is in England anyone manufacturing anthracene out of raw petroleum or the residue of petroleum distillation. I understand that anthracene is usually made from asphaltum both in England and abroad, but that the other process, mentioned above, has been introduced for some time.—J. BERNAYS.

Decolourising Property of Animal Charcoal.—Will any correspondent be good enough to inform me where the best explanation that has yet been given of the peculiar decolourising and other properties of animal charcoal is to be found. The accepted theory in all the works I have consulted appears to be that the action is purely mechanical, and due to the surface of the numerous pores. The doubt expressed by most of the authors, induces me to ask this question.—A STUDENT.

Phosphate of Lime.—(Reply to W. Tate).—On referring to Gmelin's "Chemistry," translated by Watts, you will find the equivalent of $3CaO \cdot cPO_4$ given as 155.4, while cPO_4 is there stated to be 77.4. At page 192 and following of vol. iii. of the work alluded to, you will find the theory of Berzelius alluded to based upon his experiments as regards the salt; the equivalent of $2CaO \cdot PO_4$ is stated to be 127.4, and the equivalent of $2CaO \cdot PO_4 \cdot 4HO = 163.4$. In commercial analyses, the figures quoted by you are usually taken as the equivalent of triphosphate.

Dyeing Queries.—Can any of your readers kindly give me a little information on the following subject:—I have a friend who is manufacturing cloths of enclosed kind, and he has set up a steam-box of his own, so as to tip or print his own; and I have a small works of my own, where I make extract of logwood, &c.; and I wish you to give me a formula for a good black colour, and one for a dark claret (or chocolate, as some call it)—but I want the colours to be of a good lustre after being steamed; and for full depth of colour the fine pieces are tipped with a brush, then put into a large steam-box for an hour at a pressure of 12 lbs. to the square inch; they are then taken out, all the colour washed out, and dried. Many of them are done twice over.—A. SYKES.

MEETINGS FOR THE WEEK.

MONDAY, 14th.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action."

TUESDAY, 15th.—Geographical, 8.30.

THURSDAY, 17th.—London Institution, 7.30. Dr. W. H. Stone, M.A., F.R.C.P., "On the Acoustics of the Orchestra; Wind Instruments."

Chemical, 8. Prof. N. Story Maskelyne and Dr. Walter Flight, "Mineralogical Notices."

TO CORRESPONDENTS.

A. Whitlaw.—We regret that the report of the meeting arrived too late for insertion this week.

J. Bowing.—The query is inserted with pleasure.

F. M. Jennings.—Received with thanks. The Hungarian opals will be carefully examined. They are good specimens.

THE CHEMICAL NEWS.

VOL. XXII. No. 573.

EVIDENCE CONCERNING THE GERM THEORY OF FERMENTATION

AFFORDED BY THE ACTION OF CERTAIN SUBSTANCES WHEN
SUSPENDED IN THE AIR.

By ARTHUR ERNEST SANSOM, M.D.

In the controversy respecting the origin of life, which has recently occupied much of the time of scientific men, and has called forth much warmth of advocacy on either side, great stress has been laid upon the evidence afforded by the action of heat as a means of destroying vital manifestations. It has been urged as impossible that any living matter can, after subjection to a temperature of more than 307° F., continue to manifest any signs of vitality. Some objectors have demurred to the conclusion that *all* the possible particles in the fluids employed were by the conditions subject to this high temperature; others, while accepting the premisses, have objected to the conclusion. It is well known that living matter has powers of persistence and resistance which no *primâ facie* considerations would suggest.

It is admitted that living matter can be exposed to sudden extremes, from freezing to boiling, without losing the germinating faculty.* It can scarcely be wondered at, therefore, that some persons hesitate to adopt the alternative conclusion that living things can be generated "spontaneously"—i.e., from dead matter and ordinary physical forces. It may, at least, be urged that the conclusions obtained from the evidence of heat should be tested by the results of the employment of other agents of vital destruction.

In the late controversy, such influences seem to have been ignored; but, among these, many useful-lessons may be learnt by a consideration of the destructive influences of chemical and of poisonous agents. It was known, from very early ages, that certain substances added to matters undergoing fermentation or putrefaction† put a stop to these processes. The process of embalming, for the prevention of putrefaction of the human body, is an example which dates from the greatest antiquity. Emanations from putrid material have been always looked on as sources of danger to health, and various applications have been made to putrefying materials with the object of arresting putrefaction. Sir John Pringle and Dr. Macbride, in the last century, classified such substances as arrested putrid emanations under the title of Antiseptics; these observers, moreover, performed many experiments with regard to them, and endeavoured to ascertain their relative values. There have been various theories advanced to account for the mode of operation of these various bodies in restraining putrefactive changes, and usually their action has been considered, in some sort, a chemical one—they either oxidise, deoxidise, or chemically unite with the putrescible material. But we should imagine, if a chemical agent arrested putrefaction or fermentation in virtue of its chemical powers, there should

be some sort of quantitative relation between its potential activity and the constituents of the substance itself. At least, we should imagine that, in the one case, it should be present in sufficient proportion to produce some appreciable chemical change upon the bulk of the nitrogenous substance, in the case of putrefaction, or the ferment or the fermentescible substance in the case of fermentation. But the facts are, that substances present in such feeble amounts as to be incapable of any manifest action upon the organic material, are, nevertheless, competent to arrest all the phenomena of putrefactive or fermentive decomposition.

Let us turn to the theory which proposes to explain the phenomena, on the supposition that they are produced by the acts of life of organised particles.

We see, by very obvious data, that there is an analogy which cannot fail to be remarked between the phenomena of the two processes and the conditions which we know to be favourable to vital organisms—air, light, warmth, moisture—these are the conditions most favourable to the changes. Conversely, circumstances antagonistic to life are unfavourable to the changes; such are an excess of heat or a very low temperature, dryness, physical injury (trituration yeast in a mortar spoils it for effecting fermentation). Gases which do not support life stop the phenomena of putrefaction and fermentation: such are hydrogen, nitrogen, carbonic acid. Furthermore, not only there is a definite relation between the stage of growth of the yeast fungus and its power of exciting fermentation, but, in the words of Professor Miller, "everything that destroys the vitality of these organised bodies destroys their power of exciting fermentation."

Also, with regard to mildew formation. As M. Béchamp showed, whilst mildew was developed on every occasion when air acted on putrescible material, and no substance fatal to organisms was present, no mildew was observed when any substance which killed germs was present. But here Professor Hallier steps in and shows that many saline solutions which might, *a priori*, be deemed likely to exert toxic influences nevertheless—some to great extent others slightly—permit the growth and development of fungi. Acetic acid, when dilute, permits growth, and its salts afford admirable pabula for penicillium growths. The same is true of oxalic acid and the oxalates. Vegetating fibres are also found in the alkaline and earthy chlorides, and in boiled sea-water. The phosphates, also, are very favourable for vegetation. Tannin is a good pabulum; and cyanides readily permit growth. The mineral acids, only when very dilute, permit any vegetation; but their salts often allow growth of penicillium, &c.

On the other hand, alcohol, benzol, and carbolic acid are powerful poisons to fermentation-cells and mildew formations.

Carbolic acid acts *solely* by killing the organised bodies which are the intermediate agents between organic material on the one hand, and the inorganic ultimate products of decomposition on the other. What bearing does this conclusion have on the controversy concerning the origin of life? While it puts aside all notions of intermediate chemical changes as favouring the spontaneous evolution of organisms, the objection may yet hold that the *initial* changes may yet be heterogenic, though the carbolic acid exerts its toxic power when once a molecule has acquired vitality. To obtain some evidence on this question as well as to endeavour to fix the action of carbolic acid in its relation with other media, the following experiments have been performed by the author:—

Expt. 1.—Freshly made maceration of lean beef was kept in bottles, A, in contact with ordinary air; B, in air containing the vapour of carbolic acid. A showed usual signs of putrefaction; at the end of twelve days was of extreme fetor, and presented upon its surface a dense film which, when examined by the microscope, disclosed myriads of microscopic organisms. B in its whole extent was clear and transparent, and possessed no odour save that of carbolic acid; the film instead of being made up

* "Les infiniment petits possèdent donc, pour la plupart, une résistance souvent surprenante au chaud et au froid. Une expérience de M. Pouchet montre même que certains d'entre eux peuvent supporter facilement des brusques changements de température, franchir un intervalle de plus de 100 degrés!" Pennetier, *Origine de la Vie*.

† It should be premised that there are two theories concerning the nature of fermentation and putrefaction. According to the one, these processes are essentially chemical, and are the results of the actions of nitrogenous organic bodies undergoing molecular (catalytic) changes. According to the other, they are due to the acts of life of vitalised (fungoid) particles. For a statement of the arguments, the reader is referred to a paper which will appear in the next number of the *Quarterly Journal of Science*.

of a congeries of minute organisms, was a basis structure of an exceedingly delicate and perfectly transparent membrane. It entangled here and there a few aggregations of monads.

In this case no effort was made to destroy any possible germ in the meat infusion; only in one case the air contained a poisonous agent, and here a marked repression was exerted upon the appearance of forms of life and upon the process of putrefaction.

(To be continued).

EXPERIMENTS UPON SUPERSATURATED SOLUTIONS OF SODIC SULPHATE.

By ARCHIBALD LIVERSIDGE,
Associate of the Royal School of Mines.

Review of Theories.

BEFORE drawing attention to the results furnished by my own experiments, it will, perhaps, not be out of place to pass in review the various theories which have been put forth in explanation of the action of nuclei upon supersaturated saline solutions. This I do because my experiments are supported by some and not by others of these theories. In 1809, Ziz, of Mayence,* came to the conclusion that a crystal of sodic sulphate was the best nucleus for a supersaturated solution of that salt.

Gay Lussac, in 1819, was of opinion that the sudden crystallisation of a supersaturated solution was due to a purely mechanical force, such as the agitation of the liquid within the containing vessel.† "La cause générale qui produit la sursaturation étant évidemment la même pour chaque sel, il suffira d'observer cet effet dans ceux où ils se montrent avec la plus d'intensité On ne peut assigner le terme auquel la sursaturation s'arrête: ce terme, dans chaque expérience est tout-à-fait accidentel, il dépend de la nature du vase, de son poli, de sa propriété conductrice, de l'agitation de l'air. . . . Or, puis qu'on détermine la cristallisation dans cette dissolution sur-saturée de carbonate de soude par une légère agitation il faut que la sursaturation dépende non de l'affinité, mais d'une force purement mécanique; car le mouvement ne peut par lui-même produire des effets chimiques."

Löweli,‡ in 1850, referred the phenomena exhibited by supersaturated solutions to some mysterious catalytic action of the air and other bodies.

In 1851, M. Goskynski|| propounded the theory "that the upper layer of the liquid lost water by evaporation," by this means small crystals were set free, which formed centres of attraction from which crystallisation was propagated throughout the mass of the solution.

Gernez, in 1865, was convinced that nuclei acting upon solutions of sodic sulphate, consisted of particles of that salt which were disseminated throughout the atmosphere.

And respecting the presence of this salt in the air, he says:—"La présence de cette substance dans l'air n'a du reste rien d'extraordinaire, si l'on remarque que l'acide sulfureux et l'hydrogène sulfuré produit dans l'atmosphère se transforment facilement en acide sulfurique, et que le sel marin, provenant de l'eau de la mer, doit donner avec cet acide du sulfate de soude.§

In a later paper¶ he states that supersaturated solutions of alum, plumbic acetate, zincic sulphate, sodic hyposulphite, &c., can be kept fluid in open flasks for a longer time than sodic sulphate, on account of the less uniform diffusion of particles of those salts in the air.

M. Violette also arrived at about the same results, independently of Gernez.* He states that the activity of the nucleus is destroyed on exposure to a temperature of 33.5 or 34° C., it is dissolved or modified by water, Cl, Br, most gases, alcohol, ether, &c. He says that the air at all places and under all conditions does not equally contain these crystalline particles, just as M. Pasteur has shown is the case with organic germs. In some places the particles which provoke crystallisation are, at times, altogether absent.

M. Jeannel (*Comptes Rendus*, lxi., p. 412), attributed the crystallisation of supersaturated solutions to purely physical causes, and not to the action of a particle of the same salt.

M. Dubrunfaut† thought that the formation of the salt containing ten atoms of water was directly determined by the presence of such a crystal acting as a nucleus.

M. Lecoq de Boisdaun† also experimented and wrote upon the phenomena presented by supersaturated saline solutions; he attributed nuclear properties to both the crystals of the normal sodic sulphate and to its isomorphs.

In 1868 a paper was communicated to the Royal Society, by Mr. Tomlinson, to show that the effects, attributed by earlier observers to various causes, depended solely upon want of chemical cleanness in the body which acted as a nucleus.

In this and subsequent papers the following definitions were given:—

"A nucleus is a body that has a stronger attraction for the gas, or the vapour, or the salt of a supersaturated solution than for the liquid that holds it in solution."

"Nuclei with certain limitations cease to be such when made chemically clean. A body is chemically clean the surface of which is entirely free from any substance foreign to its composition. Thus, oils and fatty bodies are chemically clean if chemically pure."

The limitations above referred to are two. "(1) Oils, fats, &c., when chemically clean, do not act as nuclei when in the mass, such as a lens or globule, but these oils, &c., whether clean or not, act powerfully as nuclei when in the form of thin films." The second limitation is connected with solutions of gases with which we have nothing to do here.||

Again, "an active or non-catharised surface is one contaminated with a film of foreign matter, the filmy condition appearing to be necessary to secure that close adhesion which brings about the nuclear action."§

From the foregoing it appears that, in the main, three theories have been offered with respect to the action of upon supersaturated saline solutions.

I. That the crystallisation of a supersaturated solution is due to the entrance of a particle of the same salt.

II. That the crystallisation set up in such solutions is due to some unknown catalytic force.

III. Nuclei are fatty, oily, greasy, or other matters, in the state of thin films.

I will now proceed with the results furnished by my own experiments. It may not, perhaps, be superfluous for me to first give the method used in preparing the supersaturated solution of the salt.

Preparation of the Solution.

The re-crystallised sodic sulphate of commerce was dissolved in tap water; filtration was unnecessary, the salt as used being free from dirt; in some cases the solution was prepared in separate 2 oz. flasks or a greater quantity was dissolved in a large vessel, and then divided out into smaller flasks, each of which was then boiled out, previous to being set aside on a marble slab to cool

during the night. An excess of salt was always used so as to ensure perfect supersaturation, the quantity in excess being left at the bottom of the flask or thrown down, on boiling the solution, in the form of the analogous salt. While still boiling the flask was either plugged with cotton wool, or covered with a watch-glass, as suggested by Mr. Löwell, or preferably a small beaker was used as a cover.

A great drawback to the employment of cotton wool is that filaments of it adhere to the neck of the flask, and these, on inserting a body, such as a rod or crystal, get carried down at the same time, when they cause the solution to crystallise, and thus vitiate the experiment.

The proper preparation of the solution is, of course, a point of fundamental importance, therefore I again repeat that in every case, when the substance under trial did not act as a nucleus, before accepting the results of an experiment I was careful to prove the supersaturation of each individual solution by means of a dirty rod or other body; for, as Mr. Tomlinson has remarked, a solution which is supersaturated at a given temperature, may be merely saturated at a higher.

Are Nuclei Rendered Inactive by Washing in Water?

Ziz, Gernez, and Violette say yes, but Mr. Tomlinson has lately pointed out* that although wet nuclei often do not, yet occasionally they do, act after some time, it may be several hours. Since the publication of this I have repeated many of my experiments upon them,† and am glad to say that they confirm Mr. Tomlinson's experience.

Experiments made with Thin Films.

It has been already stated that I did not find thin films active as nuclei,‡ and, in support of that statement, I subjoin the following series of experiments:—

Expt.—A glass rod was purposely made greasy, and exposed for a short time to the flame of a spirit-lamp, but not long enough to burn off all the greasy film. After cooling, it was placed in a supersaturated solution of sodid sulphate, and was allowed to remain in for some hours, but it did not set up crystallisation. On withdrawal from the flask the rod was washed with clean cold water, when its surface was shown to be still greasy by the manner in which the water ran off in places and collected into beads in others. After washing the rod in caustic alkali, the water wetted its surface uniformly.

This experiment was repeated many times and with the like results in each instance.

Expt.—The interior of a flask was made greasy, the solution boiled up in it and then allowed to cool. No effect.

When cold the inside was shown to be still greasy by the non-adhesion of the solution to the surface of the flask. A cold supersaturated solution wets a clean glass surface uniformly in the same way as water.

As a proof that the finger of itself becomes unclean and generates a nuclear action, Mr. Tomlinson cites an experiment made with rotating camphor particles (see CHEMICAL NEWS, September 2nd, p. 110), with a view to determine, "how long the finger, being made chemically clean, would remain so. The finger was first thoroughly washed in a solution of soap, then in alcohol, and lastly under a stream of water, and so dipped into water, on the surface of which camphor fragments were briskly spinning. The finger was retained under the surface of the water, and slid along about an inch in length of the surface of the glass below the water. In less than two minutes the camphor fragments were brought to rest, and they did not recover their activity."

I readily admit that this secretion of the finger may render the surface of the water unclean, and that this uncleanness may arrest the motion of camphor particles, but

I do not clearly see that because this secretion is effectual in arresting this motion, that it should also determine the crystallisation of a supersaturated solution of sodid sulphate. In the case of camphor the film may act by arresting the evaporation both from the surface of the water and from the camphor, for the latter in its movements would pick up a coating of oily matter, through which evaporation might not readily take place.

The next experiment was made in order to ascertain if the greasy film generated by the finger did become nuclear after some time.

Expt.—The finger was, first of all, made slightly greasy, then imperfectly wiped with a duster; it was now passed several times through the flame of a spirit-lamp, and finally inserted into a flask of solution; the flask was chosen with a neck of such a size that, when the last joint of the finger entered the liquid, the opening was completely stopped by the thicker part of the finger.

The flask was placed in water artificially reduced to a temperature of 40° F., and there kept for 10, 20, 30, and 35 minutes at a time, when the finger was withdrawn without crystallisation having taken place.

That the finger had not lost its film of grease was shown by the solution running off the nail every time it was

raised from the liquid, neither did the solution solidify when made to touch those parts of the flask upon which the finger had been pressed.

This experiment was repeated twelve times, and in every instance was the filmy matter of the finger inactive.

As it is sometimes found rather difficult to obtain iridescent films upon the surface of the supersaturated solution, the expedient of dissolving the oils and fatty bodies in ether was made use of. By this means a very small quantity of the fatty substance under trial was caused to cover a large area, for as the ether evaporated an excessively thin film of the less or non-volatile matter, as the case might be, remained behind upon the surface of the solution.

In order to permit the oil, fatty, or other body being conveyed to the solution without access of nuclei from extraneous sources, the contrivance figured above was employed, and the manipulation was as follows:—

The knot, *b*, was first rendered inactive by heating it in the lamp flame, the bulb was warmed, then the tube was inserted into the bottle containing the ethereal solution of oil, or other fluid; then as the air in the bulb cooled a small quantity was sucked up; this was then boiled both in the bulb and in the knot so as to destroy any nuclei which might be adhering to the bulb-tube or be contained by the fluid under trial; usually during the boiling the liquid inflamed and burnt at the aperture of the knot, but this offered no difficulty since the flame could always be blown out with ease. The beaker or watch-glass was then quickly and quietly

* CHEMICAL NEWS, September 2nd, p. 109 (1870).

† *Ibid.*, August 10th, 1870, p. 91.

‡ *Ibid.*, August 26th, p. 97.

removed from the mouth of the flask with one hand, and the bulb-tube inserted into the neck of the flask with the other; five or more minutes were then allowed for the deposition of any dust which might have entered during the uncovering; if at the end of this time the super-saturated solution still remained fluid, a drop of the liquid was expelled from the bulb-tube, either by warming the bulb with the fingers or by loosening the stopper, &c. The ethereal solution generally flattened out by the fall; if not, it was readily made to do so by a quick twist of the flask; the ether speedily evaporated, and left the oil, or fatty body, in the form of an iridescent film.

Amongst the substances used were these.

Ethereal solutions. { Citronelle oil (volatile).
Olive oil.
Russian tallow.
Castor oil.
Camphor in alcohol.
Methylated spirit.
Kreosote.
Oil of turpentine.
Ether.
Benzol.
Chloroform.

Thin films of each of the above were tried at least ten times; in every case the films were iridescent excepting those of olive oil, camphor, and tallow; in most instances the films were set aside for forty-eight hours; and as a further proof one flask of each was allowed to remain for five days and nights; in the meantime the temperature was twice lowered to 33° F. by means of ice, yet although a shower of crystals of the anhydrous salt fell, crystallisation did not ensue, still on uncovering the flasks at the end of the time, and exposing them to the air, the solutions at once became solid. Out of over 100 experiments made with thin films, not a single one crystallised until the solution was exposed, or a dirty body inserted.

May I be permitted to suggest a possible explanation of the activity which Mr. Tomlinson found to be possessed by thin films of oils and other fluids, and of their inertness while in the form of a disk or lens.

Mr. Tomlinson says, "thin fluids, such as ether, benzol, &c., may be taken up by a dropping-tube, fatty oils on a clean glass rod, and the watch-glass gently removed; a drop of the liquid is to be deposited on the surface, the tube or rod to be slowly withdrawn, and the watch-glass replaced."

To me, this method seems to have the serious disadvantage of exposing both the contents of the flask and the oil or other fluid to the air, and in such a way that, should crystallisation be subsequently set up, you have no means of telling whether it is due to the action of the oil, &c., added or to nuclei which may have slipped in during the necessary movements. For nuclei may have fallen in and been arrested by the lens or disk of oil; all the time that such nuclei float upon this surface of course they do not come in contact with the solution, neither do they, perhaps, when the lens is broken up into small globules, which, although small, are perhaps immense in proportion to the size of the nuclei; but now, on spreading the fluid out into a thin film, which is of excessive tenuity, the nuclei may penetrate through its thickness to the under surface of the film or even sink through, and then act upon the solution.

That the action which Mr. Tomlinson found set up by thin films starts from several points at once may be accounted for, perhaps, by the nuclei being scattered by the jerk necessary to spread out the fluid; otherwise, the crystallisation might, under other circumstances, have started in the horizontal projection of the flask's aperture, as it usually does when a solution is exposed to the air by the removal of the cover.

(To be continued).

ON THE
SOLUBILITY IN WATER OF THE OXALATES OF
SODIUM, POTASSIUM, AND AMMONIUM,
AT THE
ORDINARY TEMPERATURE OF THE AIR.*

By WILLIAM RIPLEY NICHOLS.

In determining the solubilities of the salts experimented upon, the method employed to obtain solutions, saturated at the observed temperatures, was as follows:—Considerable quantities of the salts operated upon—several times as much as would be likely to dissolve in the amount of water used—were put into glass-stoppered bottles, which were then half filled with distilled water, and placed in a pan of water so as to be immersed up to the necks. The operation was carried on in a room where the variation of temperature was slight, such variation being noted by means of a thermometer suspended in the pan of water.

The bottles were shaken conscientiously at frequent intervals for two or three days, and, finally, portions of the solutions were filtered through dry filters into tared flasks, and weighed. As a rule, the thermometer had indicated a constant temperature for several hours previous to the filtration.

The amount of oxalic acid in the weighed solution was determined by titration with permanganate of potassium, standardised against pure oxalic acid, and, from this result, the amount of salt dissolved was calculated.

In every case but one the salts were prepared by myself; and in every case the character and purity of the salt in question was ascertained by titrating a weighed portion of the dry salt with the standard solution of permanganate of potassium.

Oxalate of Sodium, $\text{C}_2\text{Na}_2\text{O}_4$.

This salt was prepared by neutralising a hot solution of oxalic acid with pure carbonate of sodium. The oxalic acid used in preparing this, as well as the other salts, left, upon ignition, 0.03 per cent ash.

Solubility.—Temperature at time of filtration, 13° C.

Temperature had varied, during solution, from 11° to 13.5°.

100 parts of the solution, saturated at 13°, contain:—

I.	II.	III.	Mean.
3.063	3.066	3.047	3.059

parts of the crystallised salt.
Or 100 parts of water, at 13°, dissolve 3.156 parts of the crystallised salt.
Or 1 part of the crystallised salt is soluble in 31.6 parts of water, at 13°.

Binoxalate of Sodium, $\text{C}_2\text{NaHO}_4 + \text{aq}$.

This salt was prepared by adding 58.5 grms. (1 eq.) of chloride of sodium, in solution, to a hot solution of 63 grms. (½ eq.) of crystallised oxalic acid, and re-crystallising the product deposited from the solution when cold.

Solubility.—Temperature at time of filtration, 10°.

Temperature had varied between 5° and 10°.

100 parts of the solution, saturated at 10°, contain:—

I.	II.	III.	Mean.
1.40	1.39	1.55	1.45

parts of the crystallised salt.
Or 100 parts of water, at 10°, dissolve 1.48 parts of the crystallised salt.
Or 1 part of the crystallised salt dissolves in 67.57 parts of water, at 10°.

Oxalate of Potassium, $\text{C}_2\text{K}_2\text{O}_4 + \text{aq}$.

This salt was prepared by neutralising a commercial sample of quadroxalate of potassium with carbonate of potassium, and re-crystallising twice.

Solubility.—Temperature at time of filtration, 16°.

Temperature had varied between 12° and 16°.

(The temperature had remained at 16° for several hours.)

* CHEMICAL NEWS, August 26th, 1870, p. 38.

† That nuclei can do so is shown by the rapid crystallisation of a solution when exposed to the air, although a film of oil, tallow, turpentine, &c., may cover its surface.

* From the *Proceedings of the American Association for the Advancement of Science*, 1869.

100 parts of the solution, saturated at 16°, contain:—

I.	II.	Mean.
24.73	24.89	24.81

Or 100 parts of water, at 16°, dissolve 32.99 parts of the crystallised salt.

Or 1 part of the crystallised salt is soluble in 3.03 parts of water, at 16°.

Binoxalate of Potassium, $4(\text{C}_2\text{KHO}_4) + \text{aq.}$

This salt was prepared by neutralising a certain quantity of oxalic acid with carbonate of potassium, and adding an equal amount of oxalic acid.

Solubility.—Temperature for three hours preceding filtration, 8°.

Temperature had varied between 8° and 10.5°.

100 parts of the solution, saturated at 8°, contain:—

I.	II.	III.	Mean.
3.680	3.681	3.668	3.676

Or 100 parts of water, at 8°, dissolve 3.816 parts of the crystallised salt.

Or 1 part of the crystallised salt is soluble in 26.21 parts of water, at 8°.

Quadroxalate of Potassium, $\text{C}_2\text{KHO}_4 \cdot \text{C}_2\text{H}_2\text{O}_4 + 2\text{aq.}$

This salt was prepared by re-crystallising a sample of commercial "binoxalate of potash."

Solubility.—Temperature at time of filtration, 13°.

Temperature had varied between 12° and 14.5°.

100 parts of the solution, saturated at 13°, contain:—

I.	II.	Mean.
1.774	1.784	1.779

Or 1 part of the salt is soluble in 55.25 parts of water, at 13°.

Or 100 parts of water, at 13°, dissolve 1.81 parts of the crystallised salt.

Oxalate of Ammonium, $\text{C}_2(\text{NH}_4)_2\text{O}_4 + \text{aq.}$

This salt was prepared by neutralising a hot solution of oxalic acid with ammonia-water.

Solubility.—Temperature at time of filtration, 15°.

Temperature had varied between 13.5° and 15°.

100 parts of the solution, saturated at 15°, contain:—

I.	II.	Mean.
4.028	4.076	4.052

Or 100 parts of water, at 15°, dissolve 4.22 parts of the crystallised salt.

Or 1 part of the crystallised salt dissolves in 23.69 parts of water, at 15°.

I verified the statement of Heintz,* that this salt is less soluble in a solution of chloride of ammonium than in pure water. I added chloride of ammonium to a concentrated solution of the salt, and there were deposited small crystals which gave by titration 50.93 per cent C_2O_3 , showing that they were actually the normal oxalate.

Binoxalate of Ammonium, $2[\text{C}_2(\text{NH}_4)\text{HO}_4] + \text{aq.}$

This salt was prepared by neutralising a certain quantity of oxalic acid with ammonia-water, and then adding an equal quantity of oxalic acid.

Solubility.—Temperature at time of filtration, 11.5°.

Variation of temperature, slight.

100 parts of the solution, saturated at 11.5°, contain:—

I.	II.	III.	Mean.
5.89	5.91	5.88	5.896

Or 100 parts of water, at 11.5°, dissolve 6.26 parts of the crystallised salt.

Or 1 part of the crystallised salt is soluble in 15.97 parts of water, at 11.5°.

In order to ascertain whether this salt dissolved unchanged, a portion of that remaining undissolved was

titrated with the standard permanganate, and the percentage of oxalic acid found agreed with that of the original salt.

Quadroxalate of Ammonium, $\text{C}_2(\text{NH}_4)\text{HO}_4 \cdot \text{C}_2\text{H}_2\text{O}_4 + 2\text{aq.}$

This salt was prepared by adding to half an equivalent of oxalic acid ($\text{C}_2\text{H}_2\text{O}_4 + 2\text{aq.}$) an equivalent of chloride of ammonium (NH_4Cl), as described in the preceding paper.*

Solubility.—Temperature at time of filtration, 7.75°.

Temperature had varied but slightly.

100 parts of the solution, saturated at 7.75°, contain:—

I.	II.	III.	Mean.
2.45	2.46	2.46	2.45

Or 100 parts of water, at 7.75°, dissolve 2.52 parts of the crystallised salt.

Or 1 part of the crystallised salt is soluble in 39.68 parts of water, at 7.75°.

Oxalic Acid, $\text{C}_2\text{H}_2\text{O}_4 + 2\text{aq.}$

A portion of pure crystallised oxalic acid was taken, and its solubility determined to be as follows:—

Solubility.—Temperature at time of filtration, 14.5°.

Variation of temperature, slight.

100 parts of the solution, saturated at 14.5°, contain:—

I.	II.	III.	Mean.
8.668	8.777	8.754	8.733

Or 100 parts of water, at 14.5°, dissolve 9.56 parts of the crystallised salt.

Or 1 part of the crystallised salt is soluble in 10.46 parts of water, at 14.5°.

ON THE

APPLICATION OF IODINE AND BROMINE

FOR THE

DETECTION OF GOLD WHEN IN MINUTE QUANTITIES.

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

THE large number of non-auriferous, or but slightly auriferous, specimens of quartz and pyritous rocks, which have lately been submitted here for examination for gold, has rendered it very desirable that some quicker, less laborious, and, if possible, more exhaustive, method of analysis, than the current one (that by amalgamation), should be employed.

In recognition of this I have frequently been urged by the director of this department to attempt some other process, and after several preliminary experiments I turned my attention especially to the use of iodine or bromine for these objects.

Both of these substances differ from chlorine especially in their relatively feeble affinities for hydrogen, so there would be the less to fear, that from the generation of hydracids, any great preponderance of other matters would be dissolved along with the gold we wish to separate from the sample under examination.

Iodine, indeed, has already been used with advantage in the analysis of certain meteorites, for the separation of the iron and nickel existing therein in a metallic state; these it combines with, leaving the associated silicates, iron-oxides, and sulphides intact.

It was this comportment of iodine with other substances that determined me to the trial of both it and bromine for the purpose named.

The results of my experiments certainly show that either of these agents may be safely and advantageously employed for the separation of gold from its matrices.

The following are the particulars of a few of these experiments, which besides their present use will, I think, be useful in showing what is, approximately, the smallest quantity of gold that can be positively separated and

identified, by a certain course of analysis operating upon a limited quantity. The first time, I believe, anything of this kind has been attempted.

1st. 2 grammes of roasted "buddle headings" from a quartz mine at the Thames, known from previous analysis to contain gold at the rate of one ounce, or so, to the ton, was well shaken for a little while with its volume of alcoholic solution of iodine (tincture of iodine of chemists), then allowed to subside. A piece of Swedish filter-paper was then saturated with the clear supernatant liquid, and afterwards burned to an ash; the ash, in the place of being white, as it would be if pure, was coloured purple; the colouring matter was quickly removed by bromine—a clear indication of the presence of gold. The time occupied by the whole process was twenty minutes.

2nd. 1 gramme of the same "buddle headings," mixed with such a quantity of soil as to reduce the proportion of gold present to 2 dwts. per ton, was allowed contact with its volume of the tincture for two hours, with occasional stirring; a piece of filter-paper was then saturated with the tincture, and dried, five times consecutively, and finally burnt off as before; in this case, also, the colour of the residual ash was purple, and it gave the reaction of gold.

3rd. 32 grammes of siliceous hematite, finely-pounded, was thoroughly mixed with precipitated gold to the amount of 2 dwts. per ton; then ignited, and treated with bromine water. After two hours the solution was filtered, and evaporated to a bulk of 20 minims; this gave a good reaction of gold to the "chloride of tin" test.

4th. 100 grammes of the hematite, with precipitated gold at the rate of $\frac{1}{4}$ dwt. per ton, treated as before, but this time well washed, at the expiration of the two hours, and the washings evaporated along with the first filtrate, gave a fainter, but still decided, reaction of gold to the same test.

5th. Iodine, as tincture, substituted for bromine in Experiments 3 and 4, gave similar results; the only variation made was, that as a precautionary measure allowing for its feebler, or rather slower, action, I gave contact for twelve hours.

To compare the results of the common amalgamating process with the foregoing, I have made some careful experiments; and I find that it is not certain, with the same expenditure of labour, to get reliable indications of gold, when present in less quantity than 2 dwts. per ton, operating upon about 100 grammes of material, which is about the quantity I usually take.

In summing up the results of these experiments, it appears, then, that for qualitative examinations for gold, or for quantitative determinations in certain cases, iodine and bromine are each superior to mercury. It also appears that a proportion of gold equal to $\frac{1}{4}$ dwt. per ton, upon a bulk of 103 grammes (about 4 ozs.) of ferruginous matters, can be easily and rapidly detected.

Of course, by operating upon larger quantities, gold could be discovered by this process, were it present in far less quantities, but this is sufficiently near for the majority of cases.

These processes are especially adapted for the separation of gold from sulphides, as the preliminary roasting is extremely favourable to them, not so much chemically as mechanically, I think; the loss in the substitution of oxygen for sulphur, amounting to 25 per cent, by weight, while the volume remains constant (or nearly so); hence there is a corresponding porosity in the product, by which it is certain every atom of it is thrown open to contact with the solution of these agents.

This mechanical accessibility obviously cannot be taken advantage of by mercury.

With sulphides these processes are practically exhaustive, while, at the same time, the simultaneous extraction of other matters is avoided, or, at any rate, is so trifling, that the proper tests for gold can be safely applied directly to the concentrated solution.

Regarding the choice between iodine and bromine, I would prefer the former, when mere traces of gold are

supposed to be present; or if the ore is in a finely divided state, as is generally the case when the matrix is iron pyrites.

In the roasting of such pyrites it is necessary to raise the temperature towards the end to a full-red heat, in order to decompose the ferruginous sulphates, since if these remained much iron would get into the solution.

In the case of much carbonate of lime being present, it is proper to gently re-ignite the roasted mineral, &c., with carbonate of ammonia, or much lime might get into the iodine or bromine solution.

On the other hand, a very high temperature is to be avoided, for, from my own experience, I find a considerable quantity of fine gold can escape detection in this way, by the partial vitrification of the more fusible of the silicates.

The identification of gold by the combustion of its salts with filter-paper, as suggested in this paper, seems to promise a rapid method of estimating it, comparatively, by the aid of a series of prepared test-papers, representing gold in different degrees of dilution.

ON THE

TREATMENT OF GELATINOUS PRECIPITATES.

By THOMAS M. CHATARD.

THE inconveniences and loss of time which attend the washing of gelatinous precipitates are familiar to all chemists. Even the methods of washing recently introduced by Bunsen are not always perfectly satisfactory in their operation when applied to this class of substances. The following method will be found, I think, to give results which leave nothing to be desired:—The solution containing the substance to be determined is to be simply evaporated to perfect dryness with a small excess of the precipitant, and the gelatinous mass stirred with a rod until it becomes a perfectly dry powder. In this manner, the precipitate diminishes extremely in bulk, and may then be washed with the greatest ease upon the filter. The evaporation is usually effected with sufficient rapidity on a water-bath. The following analyses will be sufficient to show the degree of precision attainable by this process in the cases of some of the more familiar precipitates:—Weighed portions of potassic dichromate were dissolved in very small portions of water, reduced with chlorhydric acid and alcohol, the excess of alcohol expelled, and ammonia added in excess. After evaporation, in the manner above described, the chromic sesquioxide presented a greenish blue granular powder very easily washed.

0.7782 gr. $K_2Cr_2O_7$ gave 0.4023 gr. $Cr_2O_3 = 68.02$ per cent chromic acid.

1.5646 gr. $K_2Cr_2O_7$ gave 0.8102 gr. $Cr_2O_3 = 68.13$ per cent chromic acid.

The formula requires 68.04 per cent.

Alumina, treated in the same manner, is also very easy to wash.

2.4097 gr. potassic alum gave 0.2626 gr. $Al_2O_3 = 10.89$ per cent.

1.9571 gr. potassic alum gave 0.2130 gr. $Al_2O_3 = 10.88$ per cent.

The formula requires 10.86 per cent.

The process applies with almost equal advantage to iron. Weighed portions of ammonio-ferrous sulphate were dissolved in water, and sodic chloride added in large excess, to furnish solid matter to be washed out. The iron was then oxidised with nitric acid, precipitated by ammonia, and evaporated as above.

1.5824 gr. gave 0.3229 gr. $Fe_2O_3 = 14.28$ per cent iron.

1.4840 gr. gave 0.3019 gr. $Fe_2O_3 = 14.24$ per cent iron.

The formula requires 14.29 per cent.

Nickelous carbonate also loses its gelatinous character when treated as above. 0.2201 gr. metallic nickel gave, after solution, precipitation as carbonate, and reduction by hydrogen, 0.2199 gr. metallic nickel = 99.91 per cent of the quantity taken. Cobaltous carbonate may be treated in the same manner, but the alkali cannot be completely washed out, and the method is, in this case, not to be recommended.

It seems, at least, extremely probable that other gelatinous oxides and hydrates will give equally good results when treated in the manner which I have described.—*American Journal of Science.*

ON FERMENTATION.*

By Professor A. W. WILLIAMSON F.R.S.

LECTURE I.

(Continued from p. 236).

AMONGST the processes which really are analogous to fermentation in their nature, but which differ in one particular, I must mention one other, the process of forming vinegar, or acetic acid. This large bottle contains vinegar, in a form which most of you, I dare say, have not seen. These fine white crystals are the pure substance which, mixed with water in an impure state, are generally known by the trivial name of vinegar. We call that acetic acid, or hydric acetate. The formation of this body from alcohol represents a variety of fermentation, which is of considerable importance and of frequent occurrence. Everybody who has noticed the process which takes place when animal or vegetable matter is left to itself in contact with air, especially in moist localities, must have observed that there is a gradual disappearance of the organic matter. For instance, if you leave a piece of wood in a moist place, under certain conditions of very frequent occurrence which are favourable to this process, the wood gradually gets soft, and becomes transformed into a brown substance; and, if you leave it long enough—in this country, several years generally would be needed for this purpose—it gradually disappears. If you were to put a piece of that decomposing wood into a closed glass vessel, and examine the air above it, you would find that the wood was really burning. I am using the word combustion in the ordinary chemical sense—I mean by that word that the oxygen of the air which you have enclosed with the wood is being taken up by the wood, and the products of combustion, carbonic acid and water, are being formed from the substance of the wood. One great class of the processes of fermentation is of that kind. They consist not in a mere breaking up of the materials already contained in the organic substance, but a change of their arrangements, which is due, more or less, to the absorption of oxygen; and this formation of acetic acid, or vinegar, is a case of that kind. In fact, if we were to leave some ordinary fermented wort in an open vessel, so that the alcohol were left there in the mixture in which it had been formed, we should find that the alcohol would gradually disappear, and give place to an acid substance. The process is well known to wine-makers and to brewers, and their art consists, amongst other things, in the avoidance of this process of the oxidation of their alcohol. While the acetic acid is being formed, oxygen from the air is taken up; and, in that respect, this process of acetic fermentation differs from the other three processes of fermentation which I have described. When you make alcohol and carbonic acid from sugar, the air takes no part in the process; when you make lactic acid from the sugar, the air is not wanted; and when you make butyric acid from lactic acid, then again the air may be completely excluded, and the process will go on without it. But, when you make acetic acid from

alcohol, you must of necessity allow the free and continuous access of air, and the air gives up some of its oxygen to this fermenting alcohol, to transform it into acetic acid and water by a true process of fermentation.

Now, the question arises whether this formation of acetic acid ought to be classed, as I am at present classing it, amongst the processes of fermentation. If it is due to the absorption of oxygen, you might naturally inquire whether one ought not to place it amongst the common processes of combustion, and it is right that I should state that by some authorities it is at present so classed. My reason, however, for stating what I have done, that it is a process of fermentation, is this, that it is usually affected by the action of a peculiar organism, called the vinegar-plant, an organism which I shall have occasion to show you hereafter, which does exert in that particular process the function of taking up oxygen from the air, and of inducing the alcohol to combine with it. There are many other processes by which we could get it, but the actual process by which we do get it is a process in which this vital organism, the vinegar-plant, is the agent of its formation. It might be made by mere processes of combustion, but it is made by a process of fermentation.

There is one singular feature in the first and best known of these processes—the alcoholic fermentation—which you will notice when I tell you something of the way in which the processes of fermentation present themselves, even without very great care on the part of the observer. If, for instance, you were to express the juice of some sweet fruit—say grapes—and if you were to leave that expressed juice in contact with the air for a little time, having first squeezed it through some suitable cloth or filter, so as to have it clear, of course there would be no solid particles in it when you put it aside; but, if you leave that in a tolerably warm place, in contact with the air, you would find that little solid particles would appear in this juice, that they increase in number, and that, in proportion as they increase in number, and as the quantity of them becomes greater, so does the process of effervescence—the evolution of gas from the grape juice—become more and more rapid. These little solid particles, which are not present at first in the grape juice, but which gradually make their appearance when it is exposed to the air, are what we commonly call, in the ordinary case of alcoholic fermentation, in this country, yeast—either beer-yeast or wine-yeast; it is the same organism in each case. The peculiarity of the process is this, that these substances—this yeast—which seems to make the sugar into those products which I enumerated to you, does not disappear while doing the work, but is produced by the very process. The more active the production of these yeast cells, and the more speedy the growth of these yeast cells, the more effective and rapid is the process of fermentation, and no fermentation of the kind which I am speaking of at present—the alcoholic fermentation—has ever been known to take place in the absence of these organisms. That circumstance I just mention briefly at present, but the fact that these yeast cells appear whenever the process is going on—and the more they grow the more rapid is the fermentation—has led people to suppose at first, and to believe afterwards, that these yeast cells were the agents of the transformation, the active substances which decomposed the sugar in contact with the water, and induced the transformation which we noticed. Now, the very fact that one of the two substances which are reacting upon one another chemically (because the changes are chemical in their fundamental nature), should not disappear, but should rather increase by the process, is entirely anomalous—it is entirely at variance with the simplest and best known facts of chemistry, so much so, that if it were not established upon incontrovertible evidence, I believe that most chemists would be inclined to disbelieve it, and to say it cannot be—it is impossible—it is a mistake. If you tell me, as a chemist,

* The Cantor Lectures. Delivered before the Society of Arts.

that this yeast is transforming sugar by its action on the sugar, and that, instead of being consumed, the yeast is actually increased in quantity by doing that work, I should say it is nonsense—it cannot be, because, in all the cases of chemical action which I know best, nothing of the kind occurs, but the very opposite. When one substance acts upon another, each one disappears in the process, and is transformed into a product having other properties. I need hardly give you illustrations of that; but one or two simple cases may not be useless, as serving to fix clearly this important circumstance in your minds.

I will take, at first, one of a particularly elementary and simple kind, a process of combustion. I will take a little strip of metal, magnesium wire, and will hold it for a short time in the flame of a spirit-lamp, so as to raise it to a sufficiently high temperature. The light you see emitted is due to the combustion of the oxygen in the air with the metal magnesium, which I hold in my hand. This is one of the simplest possible cases of chemical action. The metal has disappeared. The strip of wire is gone, and oxygen from the air disappeared also. At the same time a white powder was formed. I dare say you did not notice it, but here is a quantity of the same substance in a bottle. It consists of oxygen from the air combined with the metal magnesium, and the point is this—that all the magnesium which took part in that process disappeared and went to form this white powder, and all the oxygen which took part in the process also disappeared. The two united together, each disappeared as such, and went to form this new product. And, moreover, we can tell, from an examination of the proportions in which the substances combine, exactly what weight of oxygen would disappear for every part by weight of magnesium. If you burn, for instance, 3 grms. or 3 lbs. of magnesium, you would require exactly 2 grms. or 2 lbs. of oxygen. For instance, 3 lbs. weight of magnesium would combine with 2 lbs. weight of oxygen, and the product of the two together would be 5 lbs. in weight. I may show you the same thing with soda—not the substance which is commonly called by that name, which is a carbonate of that base. I have here a little pure soda solution in a bottle. I will pour some into a beaker-glass, and I will show you one property which characterises it—viz., that of changing the colour of this red paper into blue. Now, I will pour some of this acid body, the oil of vitriol, into another beaker-glass. If I put the paper which has been discoloured into this pure acid, it would be dissolved; but I will dilute some of it with water, and then you will see that paper, which has been rendered blue by the agency I have just used, is brought back again to red by the agency of this acid. Now, if I mix the acid with the soda, we shall have audible evidence of violent action going on. I will not go on with the process, but I have purposely taken the two substances in presence of very little water, in order to show you that the heat evolved makes the liquid boil with great violence. I could have avoided that by adding water in the first place, but I wished to show you the vigour with which they unite together. If I were to go on adding acid to the soda, little by little, feeling my way until I had just completed the action, I should have got some water formed and some of the beautiful salt which I have here, a body which is neither soda nor acid; it is a salt called Glauber salt, or sodic sulphate, and all my materials would have disappeared in the process. If I use them in proper proportions, all the acid and soda would disappear, and go to form these two other products. I might dissolve some of this sulphate in water, and might put red paper or blue into it, and it would not affect either of them; it is perfectly neutral in that respect. The proportions by weight in which this combination takes place is this. If I add 40 parts, by weight, of soda, and 49 of oil of vitriol in a state of purity, I should have as the result, 18 parts by weight of water, and 71 of sodic sulphate; and, if I

add together the weight of my materials and the weight of my products, I get the same—89. Nothing disappears in the process; all the acid and all the base which takes part in it is employed. Each particle which took part in the process disappeared as such, and it passed over into another form.

I will mention one other case, because it is somewhat more complex. I may take the case which I was showing you just now, the white marble and hydric chloride, or muriatic acid, which I used for making the carbonic acid gas. In that case, I used two materials, carbonate of lime, as it is commonly called, and hydrochloric acid. We get three products—on the one hand is a salt, which is commonly called chloride of calcium, a solid substance used for drying gases, as it has a great affinity for water; another is water; and the third, as I showed you, carbonic acid gas. There, again, we have precisely the same thing. All the marble and all the hydric chloride which takes part in the formation of those three products disappeared as such, and they resolved themselves into other compounds possessing different properties; but the weight of the products is equal to the weight of the materials. That rule holds good throughout all ordinary cases of chemical action.

On the other hand, in fermentation it is not so; one of the active substances is formed, and the more active the fermentation, the more does it grow. In fact, if you want to get yeast, you must go to a place where the breaking up of sugar into alcohol and carbonic acid is going on; or, if it is in the south, you must go to where wine is being made—you go to a wine-maker and get the yeast from him. The only way of getting yeast is from that process of fermentation which sets in spontaneously under the conditions I named to you.

(To be continued.)

DR. SEYFERTH'S PROCESS FOR THE PURIFICATION OF SYRUPS AND MOLASSES IN THE MANUFACTURE OF SUGAR.

THE juices and liquors employed in the first extraction of sugar from the raw material it is contained in, as well as the syrups resulting from the sugar refining processes, all generally contain a certain quantity of alkaline substances, varying, however, in quantity with the various conditions of the soil on which the beet-roots have been grown and the mode of cultivation. The juice of the ripe sugar-cane, however, is at the moment of being squeezed out of the cane slightly acid to test-paper. By treating the saccharine juices with milk of lime, several of the bases of the alkaline salts present in the juices are separated from the acids they were at first combined with, and by thus being set free and remaining mixed with the sugar, impede its crystallisation. One part of alkaline matter can absorb as much as four parts of sugar; and some kinds of molasses (chiefly from beet-root) contain as much as 8 per cent of alkali.

The means hitherto tried to remedy this defect, viz., neutralisation of the alkalies by acids, have failed in practice, chiefly for two reasons: first, because the acids have not been applied at such a stage of the process of manufacture as to enable the acids to seize upon the whole of the alkalies; and secondly, because it has never been possible to prevent the injurious effect of even a very slight excess of acid upon the sugar itself; while, moreover, a difficulty is encountered by the very variable quantity of alkali present, whereby the proper quantity of acid to be applied varied every moment, thus rendering their application totally unsuited in any but very skilled hands. Among the acids applied sulphuric and phosphoric have been most used, but their use could not but be very limited, since even a very slight excess thereof was far more to be dreaded, on account of its highly injurious

effects upon the sugar, than almost any amount, so to say, of alkalies. Sulphurous acid has been used and recommended in various forms, even as far back as 1810 (Proust), both on account of its activity as acid in saturating alkalies, as well as its power as a bleaching agent, by thus rendering the sugar more white-coloured.

Dr. Auguste Seyferth, managing-director of the Brunswick sugar (beet-root) refinery, has hit upon a plan for the use of sulphurous acid, which, according to the unanimous and unbiassed testimony of no less than 100 proprietors of establishments wherein the process invented and brought out by the Dr., since September, 1869, is applied, answers the purpose admirably, yielding more produce and of better quality in every respect. The process alluded to consists essentially in the introduction of sulphurous acid, either in gaseous form, or in very weak aqueous solution, into the vacuum pans. By this arrangement it is possible to bring all particles of the sugar solution (syrup) into contact with sulphurous acid, and to eliminate, by the joint action of heat and vacuum, any excess of that acid, which, however, not only saturates free alkalies and carbonate of lime, but also sets the organic acids, which might be present as alkaline salts, free from these combinations; the sulphurous acid taking hold of the bases they were combined with, while the greater part of these organic acids are volatilised along with the steam, and thus the sulphurous acid promotes the good and ready crystallisation of the sugar, while its action as a decolouriser comes also advantageously into play.

The Seyferth process embraces two main operations, viz., the manufacture of the sulphurous acid as gas, or as aqueous solution, and the application of the acid (chiefly in aqueous solution, being more readily manageable) and its introduction in the vacuum pans. The sulphurous acid is manufactured at the works (beet-root sugar manufactories or sugar refineries) by the well-known expedient of burning sulphur in suitably constructed ovens, and carrying the products of combustion, previously cooled so as to condense any vapours of sulphur, into a leaden vessel wherein the gas is met by a suitably arranged current of water so as to become entirely absorbed. The aqueous solution thus obtained is put into casks, or other suitable vessels, and from these a tube, provided with taps, leads to the vacuum pans, wherein the liquid is sucked simultaneously with the sugar solution. The party in attendance upon the boiling in the vacuum pans, while causing the sulphurous acid to be aspirated, takes care to test from time to time (this is done by means of the contrivance technically known as proof-stick) the contents of the pan by applying blue litmus paper, so as to ensure the contents of the pan remaining alkaline; but if by a mishap the acid is in excess, this is remedied by sucking in a fresh quantity of sugar solution, while a slight increase of the rapidity of evaporation (the turning on of more cold water to the condensers) will rapidly eliminate and volatilise any excess of sulphurous acid, which, when in quantities of 50 to 100 kilos, excess of the weak solution, does not affect the sugar.

The quantity of sulphurous acid solution applied varies from 4 to 8 or from 10 to 15 per cent of the bulk of liquid (syrup) to be evaporated, but these figures are not absolute but only relative, since experience has already proved that the requirements differ for different localities. The process alluded to is stated to possess, besides the advantages already named (production of better quality and larger quantity of sugar), the good qualities of being applicable at very little cost; to require no inconveniently large space; to be applicable to any already existing manufactory without causing any temporary stoppage of work; its application is readily learned by the sugar boilers. According to the communications made on this subject by the members assembled at the general meeting of German sugar manufacturers and refiners, at Berlin (last May), and a similar meeting lately held at Prague, this process is highly appreciated, and largely eulogised as an immense improvement in this branch of industry.

CONTRIBUTION TO AN IMPROVED METHOD OF ANALYSING MINERAL WATERS.

By Dr. MOHR.

WHEN large quantities of an alkaline mineral water are evaporated in a porcelain dish, the saline matters, chiefly carbonates of the earths, form a crust at the bottom of the vessel, so fixed that it is impossible to loosen it, while it need hardly be said that the residue cannot be weighed, while in the large basin, with accuracy. The author, therefore, adds to the water a sufficient quantity of formic acid, so as to render the fluid distinctly acid to test-paper, and then proceeds with the evaporation cautiously, and finishing it on a water-bath or in the drying box; the residue is taken up with a small quantity of distilled water and the solution filtered through a small filter, the filtrate being run into a platinum crucible, or basin of sufficient size, yet at the same time suitable for accurate weighing. The filter contains all the silica that was contained in the water, and, after washing and drying that substance, is readily estimated by well-known methods.

The filtrate in the platinum vessel is evaporated to dryness, and gently heated to redness; the formic acid does not, as acetic acid does, leave a carbonaceous residue, but is entirely converted into volatile compounds, viz., two atoms of carbonic oxide, and one atom of water; all the salts, therefore, which the mineral water contains, are, after the heating to redness, converted to the same condition they were in before the addition of the acid, and the residue, after weighing, is treated with boiling distilled water; this solution is filtered, and the insoluble residue on the filter treated by the well known methods.

The soluble soda-salts contain, or rather are combined with, carbonic and sulphuric acids and with chlorine; in order to estimate with the same quantity of substance each of these three acids, the author suggests the following method:—The aqueous solution of the salts is boiled, and, while boiling, a neutral solution of acetate of lime is cautiously and drop by drop added, so as to decompose the carbonate of soda with the formation of carbonate of lime in the form of arragonite; the carbonate of lime is collected on a filter and to the filtrate is added acetate of baryta, while the fluid is kept in ebullition; the precipitate sulphate of baryta is collected again upon a filter, serving the purpose of the estimation of sulphuric acid; in the filtrate the chlorine is estimated by means of nitrate of silver, the solution having been acidified, previous to the addition of the solution of that salt, with nitric acid.

In this manner three different precipitates are obtained, from each of which the calculation for the corresponding soda-salts is made. Carbonate of lime $\times 1.06 =$ carbonate of soda ($\frac{53}{50} = 1.06$). Volumetrically, the carbonate of soda is first estimated with the aid of tincture of cochineal and 1-10th of nitric acid; in the same fluid chlorine is volumetrically estimated by means of a solution of chromate of potassa, and 1-10th of nitrate of silver solution; after the addition of chlorhydric acid, the solution is filtered and the sulphuric acid in the filtrate is estimated gravimetrically by well-known methods.—*Zeitschr. für Anal. Chem.*

PROCEEDINGS OF SOCIETIES.

GLASGOW PHILOSOPHICAL SOCIETY. (CHEMICAL SECTION).

THE opening meeting of the session took place on Monday night in the Lecture Hall, Corporation Buildings. Alexander Whitelaw, Vice-President, delivered the introductory address.

After making a feeling allusion to the death of Dr. Penny,

Dr. W. Allen Miller, and Dr. Matthiessen, and expressing regret at the loss which chemical science has sustained thereby, Mr. Whitelaw proceeded to notice some of the most recent discoveries and improvements in industrial chemistry. Among others, he referred to Mond's process for the recovery of sulphur from alkali waste, Weldon's continuous method of obtaining chlorine, Deacon's process for making chlorine without the use of manganese, by passing hydrochloric acid gas over hot bricks saturated with sulphate of copper, whereby, by a peculiar reaction hitherto unknown, water and chlorine are produced, while the copper salt remains intact and active for an indefinite time. After touching on various points of interest with regard to the utilisation of certain by-products, Mr. Whitelaw described a new process now in operation on a large scale for the recovery of the small quantity of the precious metals in the copper liquors obtained from burnt Spanish pyrites, by Henderson's process. He also described the process for the manufacture of ferro-manganese or spiegeleisen, from the residual oxide of iron from the above process. Passing to organic chemistry, Mr. Whitelaw described a new discovery, by Bock, of Copenhagen, and now in operation for the manufacture of stearic acid without either lime saponification or distillation with superheated steam. Before concluding, Mr. Whitelaw shortly reviewed a recently-published "Digest of the Sewage Question," prepared for the committee of the British Association, and stated that, after a careful study of the whole evidence, and notwithstanding rather strong preconceived opinions to the contrary, he was forced to the conviction that the soil is the only perfect purifier of sewage—that intermittent filtration through the soil—in other words, irrigation by sewage—is the only thorough way of utilising the manurial matters contained in, and sweetening the effluent waters from sewage. That sub-soil, water, and rain-water should be, if possible, run by means of deep drains into the nearest water-course; and that the house-sewage should be conveyed by means of pipe sewers of moderate size, capable of being flushed to the out-fall works, there to be roughly filtered before being used for irrigation. Mr. Whitelaw then read extracts in support of his opinion that sewage farms are not hurtful to health, but are, on the contrary, if properly managed, the reverse.

NOTICES OF BOOKS.

Snuff-Taking: its Utility in Preventing Bronchitis, Consumption, &c. (With prescriptions.) By JOHN C. MURRAY, M.D., F.A.S.L. London: J. Churchill and Sons. Newcastle-on-Tyne: D. H. Wilson. 1870.

THIS essay is an extension of a paper read before the Medical Section of the British Medical Association, held at Newcastle-on-Tyne in August last, and the subject it treats of is fairly and scientifically put forward. It is divided into seven chapters, and contains, moreover, a large appendix, including prescriptions and correspondence. The author has done good service in calling the attention, not only of medical men, but also of the public in general, to the subject of snuff-taking.

Elementary Questions in Chemistry for Students. First series: Thirty Papers on Heat and Metalloids. By THOMAS WOOD, Ph.D., F.C.S., Lecturer on Chemistry at the Brighton and Lancing Colleges, &c. London: J. Helm, 10, Brownlow Street, Holborn. Brighton: H. C. Treacher. 1870.

THERE are two methods of giving young people instruction in chemistry, in the absence of a regular working laboratory. First, by lectures only, without any examination or further notice of the subject. This plan awakens interest in the pupils, teaches them to observe, enlarges their ideas, acquaints them with many things necessary

for everyone to know, and is comparatively of much use; but it is almost valueless as far as really mastering the science is concerned. Secondly, by lectures given in the regular school hours, partaking more of the nature of an ordinary school lesson, where any boy may be asked questions during the lecture, and an examination on each lecture is held immediately afterwards—the examination being made compulsory, like any other work. For some years past the plan has been followed at the Brighton College of setting the examination paper *before* the chemical lecture is delivered, the lecturer answering, in the course of his lecture, each question on the paper. The boys subsequently answer the questions in writing, each master looking after the answers in his form. Such success has attended this plan that Dr. Wood has been induced to print these questions, so that a similar plan may be followed at other schools. It is proposed to print three series of questions in sets of ten, of which the present series is the most elementary. The first series of papers requires lectures illustrated by simple experiments, intended only to teach plain facts and give elementary information, such as shall enable the pupil eventually to grasp the principles of the science in a more advanced course of study. The second series will enable the examiner to see if the boy has intelligence and ability sufficient to put the facts together which he has learnt in the first course of lectures, use them in a rational way, and understand the principles on which the science is built. The third series will be a set of still more advanced questions, requiring the student to use his reasoning power, and to apply the principles of the science with accuracy to new cases. The series before us is intended to accompany a first course of lectures, and is so arranged that each question requires only a single answer, and many of them may be answered by a word. The author's little book is published very opportunely, now that the Elementary Education Act is about to come into operation.

We sincerely hope that enlightened, liberal minded, and clear headed men will be elected as members of the Education Board, and that they will see that the first and foremost point in education is to make children well grounded in the elements of all branches of knowledge. Chemistry pertains especially, along with other physical sciences, to the subjects of sound elementary education, which ought to be thoroughly unsectarian, in the fullest and strictest sense, so absolutely that even Mahometans or Buddhists from India, as well as Jews and Christians, can attend the school and study together. The example of the United States, of Switzerland, Belgium, and the Netherlands, as well as of other countries, proves, not only the possibility, but also the perfect fitness, of this arrangement. And it should not be forgotten that, as regards the teaching of the elements of physical and natural history sciences, they widen a man's views, sharpen his intellect, and give him power in various ways; and this power, rightfully and judiciously applied, cannot fail to benefit the individual, as well as the agglomeration of individuals, termed the nation.

CORRESPONDENCE.

PRESERVATION OF STONE.

To the Editor of the Chemical News.

SIR,—In a letter by Mr. A. H. Church, which appeared in the last number of the CHEMICAL NEWS, the originality of my proposal to apply the superphosphate of lime as a means of preserving stone from decay is called in question, and the report of the Chemical Sub-Committee (Houses of Parliament) is cited, as proving a prior use, in this country, of phosphoric acid and the superphosphates for the purpose mentioned. But Mr. Church has failed to notice that this report bears date June 17th, 1861—one

month later than my proposal (May 13th)—and that it is to my process that reference is here made in the report. I have Coignet's specifications now before me, and no mention is made of the superphosphate being applied to stone, but only to the surface of large artificial blocks, for the purpose of enabling them to take a coat of paint.

If Mr. Church (or Mr. Ransome) believes he has secured a good patent for a "Combined Process," embodying your own dialysed silica and my superphosphate, what is to prevent me from patenting an "Improved Combined Process," which differs only from his by finishing up with a last wash of superphosphate applied upon the other ingredients? This would prove quite successful, but, in the event of such a course being permitted, to what monstrous absurdities would the Patent Laws of England be lending support!—I am, &c.,

JOHN SPILLER.

London, Nov. 14th, 1870.

MISCELLANEOUS.

Method for Repairing Porcelain Evaporating Basins when Cracked.—Dr. Walzl recommends, first to dry the vessels thoroughly in a drying-stove, and next to fill them with a rather concentrated solution of silicate of soda and leave the solution in the vessel for about twenty-four hours after the liquid has been poured out. The vessel is gradually dried at a gentle but increasing heat, and it will then be found to hold liquids again and be fit for further use.

Cleaning Oil Painted Surfaces.—Take a piece of soft flannel, put it in warm water, and squeeze it till it feels dry; next dip it gently on to some very finely pulverised French chalk, and rub the painted surface with the flannel; the effect will be the removal of all dust, greasy matter, and dirt; the surface is next washed with a clean sponge and water, and dried with a piece of soft wash-leather. This method does not injure the paint like soap, and produces a very good result.

Testing Carbonate of Lead for its Goodness as an Ingredient of the Manufacture of Crystal Glass.—Dr. A. Neujean.—Since the presence of iron and copper are the only impurities which interfere with the use of white lead for the purpose above-named, the author tests for the presence of these substances colorimetrically in the following manner:—From 20 to 40 grms. of the substance (white lead), if apparently very pure, and only 10 grms. if obviously impure, are dissolved in dilute sulphuric acid, and next precipitated by means of sulphuric acid; the liquid having been filtered is evaporated and reduced to a small bulk, and next, by the addition of water, made up to a constant volume, after which a few drops of sulphocyanide of potassium are added; the presence of copper is tested for by a similar operation, ammonia being applied instead of the salt just alluded to.

Preparation of Tannic Acid.—O. Rothe.—The author recommends the following process as the best and simplest:—Eight parts of pulverised nut-galls (the Chinese galls are preferred by the author) are macerated for two days in a mixture of twelve parts of ether and three of highly rectified alcohol, care being taken frequently to move the vessel containing the mixture. The liquid having been poured off from the residue, the same quantity of ether and alcohol is poured on the powder, and, after a short maceration, the pulpy mass is pressed; the mixed liquids are left at rest for some twenty-four hours, after which there are added to the fluid twelve parts of water; this having having been done, the mixed alcohol and ether are removed by distillation, the greenish resinous matter which will be found floating on the residual liquid is removed by filtration, and after that the liquid is evaporated to dryness by means of steam and the residue ground to powder.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTES. All degrees of temperature are Centigrade, unless otherwise expressed.

Journal de Pharmacie et de Chimie, September, 1870.

This number contains the following original papers and memoirs:—

Modifications which the Alkaloids of the Cinchona Barks Undergo under the Influence of Certain Physical and Mechanical Agents.—M. Carles.—The author relates the results of some experiments made with the view to investigate the action and influence of long-continued grinding and exposure to air of the powder thus obtained of cinchona barks, and, next, the action of sunlight, moisture, and heat upon that powder. It appears that the mechanical operation of grinding, even if continued for some time, does not alter in composition, nor lessen the quantity of the alkaloids present in the bark; but exposure to sunlight in a stoppered bottle for about a month decreases the quantity of alkaloids by about 5 per cent, while the prolonged action of moisture and heat produce similar results.

Decomposition of Oxalic Acid.—M. Carles.—The contents of this paper give an account of a series of experiments made with the object of ascertaining the action of currents of pure oxygen and hydrogen upon aqueous solutions of pure oxalic acid, as regards the decomposition of that substance into carbonic and formic acids at a temperature of 100°. The author has also found that perfectly pure nitrogen has the same effect upon a solution of pure oxalic acid at 100°, dissociating it into carbonic and formic acids; but the cause of this action is not yet explained.

Modifications which Inuline undergoes, Spontaneously or by the Combined Action of Heat and Water.—M. Lefranc.—This lengthy essay treats, in the first place, on the changes which inuline suffers in the living parts of plants (chiefly roots and tubers). It appears that the inuline is gradually converted into a sugar-like substance, which the author calls *inulose*, and into soluble inuline, which, the author states, partakes, in many of its properties, of levuline. The former of these substances is optically neutral, capable of fermentation, and has the aspect of glucose. Levuline is levogyrate, not capable of fermentation, and has the aspect of starch; neither of these two substances are detected by the cupro-potassic reagent. The author states, that when inuline in solution is boiled for thirty hours with water at 100°, it yields the same products as those just mentioned as being the result of the action of the vital process of the plants upon inuline.

Experiments made with the Salts of Manganese.—A. Commaille.—This lengthy essay treats on the action of several substances (chiefly acids) upon permanganate of potassa. The essay is divided into the following sections:—Action of nitric, sulphuric, hydrochloric, iodic, arsenious, oxalic, acetic, tartaric, citric, benzoic, and uric acids upon the permanganate of potassa, the action being aided by alcohol, ether, and sometimes electricity. It is not well possible to give a succinct account of the reactions which take place in each instance, but it appears that, when the permanganate is dissolved in chlorhydric acid, and an electric current conducted through that solution, hydrogen gas is abundantly given off. The same phenomenon takes place under similar conditions with a solution of the permanganate in oxalic acid; but, without the electric current, ozonised oxygen is given off.

On Melassimetry.—M. Maumené.—This paper treats on the estimation of the value of raw sugars; its contents are reserved for full translation.

Properties of Iodic Acid.—A. Ditté.—This paper treats on some reactions of anhydrous and hydrated iodic acid. The former substance is a white-coloured powder, very soluble in water, and insoluble in ether, chloroform, sulphide of carbon, and hydrocarbons generally; sp. gr. at 0°, 4.87. The oxidising properties of this substance are very energetic. At the ordinary temperature, this action is not so manifest; but, at an elevated temperature, this acid acts energetically, even upon hydrogen (under pressure), upon carbonic oxide, sulphurous acid, and ammonia, while even at the ordinary temperature sulphuretted hydrogen gas and hydrochloric acid gas are acted upon. The monohydrated iodic acid is also a solid substance; sp. gr. at 0°, 4.629. The reactions of the concentrated solution of this acid, and its behaviour with most of the metalloids, is described at length. Benzene and acetylen are decomposed by anhydrous iodic acid at 220°, yielding carbonic acid and water.

Monobromated Iodhydrates and Chlorhydrates of Ethylen and Propylen.—E. Rebol.—This essay treats on the action of iodic and chlorhydric acids upon the substances above named. When iodic acid acts upon the monobromated ethylen at the ordinary temperature, there is only formed an iodhydrate of the monobromated ethylen; but, if the action is assisted by heat, two isomeric compounds are formed. The general result of the action of the hydracids upon the monobromated compounds of ethylen and propylen is the formation of isomeric compounds; but, whereas with bromhydric acid the degree of its concentration is in play, with iodic acid only the temperature is of any influence. Chlorhydric acid yields only one product, which is a chlorhydrate for bromated ethylen and a chlorobromide for bromated propylen.

NOTES AND QUERIES.

Answer to Query.—In answer to X. Y. Z. in your issue of the 4th November, the book he wants can be obtained of Mr. Freeman, 27, Church Street, Soho.

For Exchange.—Well crystallised specimens of the rare mineral "Atacamite," new to Britain; see last week's *CHEMICAL NEWS* for properties. For other rare minerals or copper ores. H. H., 12, Portland Place, Layerthorpe, York.

Dyeing Queries.—(Reply to A. Sykes.)—We cannot do better than to refer you to a work on "Dyeing and Printing," which the Editor of this paper has in the press; it will give you the information you require; and, in the meantime, you might consult the work named in the first line of our "Notes and Queries," No. 571; or Dr. Calvert's work quoted in "Notes and Queries," No. 568.

Decolourising Property of Animal Charcoal.—(Reply to "A Student.")—If you would read the section treating on "Bone-Black or Animal Charcoal," pp. 162 and following, in the "Treatise on the Manufacture of Beet-root Sugar," edited by the Editor of this paper and published by Messrs. Longmans, Green, and Co., you will obtain an excellent insight into the subject you desire to be informed upon.

Manufacture of Anthracene.—(Reply to J. Bernays.)—As far as the replies we have received in reference to the distilling or refining of raw petroleum go, there is at present either none at all refined in this country, or it is only done on a very limited scale. It might be that the oil obtained in the distillation of the crude ozokerite, or the residues of that distillation, contain anthracene, but we have no positive evidence to prove that, nor, as far as we have been able to ascertain this matter, is the manufacture of anthracene from these substances carried on in this country.

Deodorising Oils.—(Reply to "Nindex.")—Try the following methods:—The oil gently heated on a water-bath is stirred for some time with about 1 per cent of good chloride of lime, previously made into a milk by trituration with water; about 14 parts of oil of vitriol, previously diluted with 20 times its weight of water, is then added and the agitation renewed and maintained for at least two hours; the oil is, lastly, well washed with steam or hot water, and next filtered through charcoal; or you may agitate the oil with from 4 to 8 per cent of caustic soda lye, sp. gr. 1.2; after twenty-four hours repose the supernatant oil is decanted from the sediment and filtered.

Sulphuretted Hydrogen Apparatus.—(Reply to "Nindex.")—Since it appears that you chiefly aim at the prevention of the annoyance, caused by the disagreeable smell, your best plan is to enclose the apparatus, while in use, in a case or cupboard connected by suitable means with the flue of a chimney having a good draught; or you must contrive your working arrangements with the gas in such a manner as to absorb by suitable means, for instance by dry caustic lime, by granulated and freshly burnt charcoal, or by caustic or carbonated alkali, the excess or waste of gas; as to proper apparatus a vast number have been described, and you can select such as suit your work best.

MEETINGS FOR THE WEEK.

MONDAY, 21st.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action." (Educational Course.)

WEDNESDAY, 23rd.—Society of Arts, 8.

THURSDAY, 24th.—London Institution, 7.30. Prof. Morris, F.G.S., "On the Precious Metals and their Distribution."

TO CORRESPONDENTS.

F. Pigott.—Declined with thanks.

E. W. Farnell.—We do not see much difference between the two.

C. K. C. Treharne.—Your communication did not arrive in time for insertion this week.

F. Spence.—Unavoidably postponed till next week.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations. Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations. Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations. Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s. Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

TEXT-BOOKS OF SCIENCE.

Now ready, the first Two of a New Series of Elementary Works on Mechanical and Physical Science, forming a Series of Text-Books of SCIENCE, adapted for the use of Artisans and of Students in Public and other Schools—edited by T. M. GOODEVE, M.A., Lecturer on Applied Mechanics at the Royal School of Mines—in small 8vo., with Woodcuts, price 3s. 6d. each Work.

Metals, their Properties and Treatment. By Professor BLOXAM.

Elements of Mechanism. By T. M. Goodeve, M.A.

*** The Prospectus, with the List of other Works in preparation in the Series, may be had of all Booksellers.

London: Longmans, Green, and Co., Paternoster Row.

On Tuesday next, with 13 Illustrations, price 10s. 6d.,

Other Worlds than Ours; the Plurality of Worlds Studied under the Light of Recent Scientific Researches. By RICHARD A. PROCTOR, B.A., F.R.A.S., Author of "Saturn and its System," &c. Second Edition, revised.

By the same Author, nearly ready, uniform with the above, **The SUN; RULER, LIGHT, FIRE, and LIFE of the PLANETARY SYSTEM.**

London: Longmans, Green, and Co., Paternoster Row.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7, IRWELL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870–1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXII. No. 574.

EXPERIMENTS UPON SUPERSATURATED SOLUTIONS OF SODIC SULPHATE.

By ARCHIBALD LIVERSIDGE,
Associate of the Royal School of Mines.

(Concluded from page 241.)

The Action of Crystal of Normal Sodid Sulphate upon a Supersaturated Solution of the same.

It is a well-known fact that clean crystals of both the anhydrous salt and the modified salt ($\text{Na}_2\text{SO}_4 \cdot 7\text{OH}_2$) are inactive as nuclei in a supersaturated solution of sodid sulphate.

The following series of experiments were made, because it was found by the writer that, no matter how it was attempted to render a crystal of the normal salt ($\text{Na}_2\text{SO}_4 \cdot 10\text{OH}_2$) inactive to a supersaturated solution of the same, he could never succeed, yet such crystals of the normal salt could readily be made inactive to supersaturated solutions of other salts—as of alum, &c.

For example, let us take a supersaturated solution of alum, and one of sodid sulphate, and also crystals of both their salts, which crystals have just formed, and are taken from their still warm mother-liquors.

Expt.—A crystal of alum from its mother-liquor was added to a supersaturated solution of alum. Crystallisation immediately took place.

Expt.—A like crystal of alum was then added to a supersaturated solution of sodid sulphate. No effect.

Expt.—A crystal of the normal salt was taken from its mother-liquor and added to a solution of sodid sulphate. The solution instantly crystallised, although another crystal was inactive to a solution of alum.

Expt.—A crystal of magnesian sulphate was added to solutions of alum and of sodid sulphate, respectively. No effect on either, but active in a solution of magnesian sulphate.

Amongst the older observers, Ziz, Gernez, Violette, and others attributed the nuclear action to a particle of the same salt. Mr. Tomlinson was, I believe, the first to combat this view; he refers the activity of such a particle of the salt to the filmy impurities with which it is contaminated.

And, in proof that clean crystals are inactive, he brought forward the two following experiments:—

“Hydrated crystals of magnesian sulphate were introduced into the neck of a flask in which a solution of the salt was also being boiled. The crystals were left so suspended, while the solution cooled under cover; when cold, they were lowered into the solution, and found to be inactive.”*

Dr. De Coppet objected to this experiment, on the score that the crystals had been so changed by heat as to no longer represent the normal salt.

“In the second form of the experiment, highly supersaturated solutions in clean test-tubes were plugged with cotton wool, and, when cold, placed over sulphuric acid under the receiver of an air-pump, and left for some time *in vacuo*. Crystalline crusts of the normal (*sic*) salt formed on the surface, which, by shaking, fell through the solution, without acting as nuclei; a crystalline crust of the normal salt also crept up the sides of the tube, which was also inactive because chemically clean.”

But Löwel says that it is not the normal salt which is formed on allowing a supersaturated solution to evaporate spontaneously under cover,† but the modified salt, or that

with seven atoms of water; and, in proof of this, he gives experiments and analyses of the salt thus formed.

And, further, he says—“Mais ce qui paraît certain, c'est que, sans cette action mystérieuse que l'air et les autres corps exercent sur les dissolutions, nous ne connaîtrions le sulfate de soude qu'à l'état que j'ai appelé *modifié cristallisant avec 8 équivalents d'eau*.”

The following experiment was made upon this point:—

Expt.—A tubulated bell-jar was fitted with a cork bearing a glass tube, which was open below and closed above; the lower end was made inactive, by means of the lamp-flame, and allowed to cool, then a flask of solution was placed under the bell. After the lapse of five minutes (in order to ascertain if nuclei had gained access), the tube was inserted and withdrawn, bearing with it a little of the solution. A capsule of sulphuric acid was next placed under the bell, when evaporation rapidly took place from the small quantity of solution on the tube, upon and within which a crust and plug of crystals were formed, and these were coated with a white pellicle of the effloresced salt. On again lowering this tube and its adherent crystals into a solution no effect was produced.

This experiment was repeated again and again, and with the same unvarying result—*i.e.*, the crystals produced by evaporation were inactive, which inactivity seems to be only explicable by accepting Löwel's analyses, especially as, in the experiments about to be detailed, the normal salt was invariably found to be active.

Next, experiments were made with recently-generated crystals of the normal salt.

Expt.—Two beakers, containing fully supersaturated solutions, were covered with watch-glasses, and allowed to cool; in one of the beakers, a small glass bucket, attached to a thread, had been placed and boiled up with the solution. Next, both beakers were arranged under a large bell-jar, and the silk thread from the bucket passed up between the stopper and the neck of the jar. The solutions were then uncovered, after waiting ten minutes for any nuclei which might have been disturbed to fall; a fine wire was passed down into the beaker containing the bucket, and as far as possible from the part of the solution through which it would pass on being drawn up.

The bucket, now full of the crystallised normal sodid sulphate ($\text{Na}_2\text{SO}_4 \cdot 10\text{OH}_2$), was raised, and lowered into the second beaker of still fluid solution; immediately that the point of one of the crystals hanging from the under surface of the bucket touched the solution, crystallisation was set up instantaneously throughout the mass.

This experiment was performed many times, and with every possible care to prevent the entrance of nuclei other than those purposely borne by the wire.

A modification of the above plan was tried, and with similar results.

Expt.—A tubulated glass bell was fitted with a cork bearing two glass tubes, open below and closed above with cotton wool; they were bent, so as to permit both of them being placed in one and the same beaker, or into either separately.

In the first place, the ends of the tubes inside the bell were freed from nuclei, by passing them through a flame; two beakers of cold supersaturated solution were then placed in position under the bell-jar, and their covers removed. After waiting five minutes or so, for any dust to settle, both tubes were next lowered into one of the beakers, on opposite sides, so as to be as far apart as possible. A dirty wire was now passed down one of the tubes, when, of course, crystallisation immediately took place, and was propagated across the beaker. The second tube, with its adhering crystals, was then raised and lowered into the second beaker, when, the moment the extreme point of the longest crystal touched the surface of the solution, crystallisation immediately started from that point, and the whole contents became solid.

A third variation was then made in this experiment. One of the two beakers was replaced by a U-tube of thin,

* *Phil. Trans.*, 1868, p. 661, and *CHEMICAL NEWS*, vol. xviii., p. 110.
† *Ann. de Ch. et de Ph.*, 1850, vol. xxv., p. 126.

hard glass, one of the before-mentioned tubes being inserted into either limb. Crystallisation, when set up in one limb, travelled round the bend and up into the other, from which crystals were transferred, as before, to a beaker or flask of solution also under the bell-jar.

The three modifications of this form of experiment were tried time after time, and always with the same unvarying result. Solutions which were supersaturated although not perfectly, and therefore less sensitive, were operated upon in this way; but, even with such less favourable circumstances, the normal crystals always started crystallisation in the solution to which they were added.

To ascertain, if possible, whether nuclei, other than crystals of the normal salt, were carried by the tube or its adhering crystals, a capsule of sulphuric acid was placed under the bell. The crust of crystals was, by this means, dried, and became effloresced to a greater or less extent. Now, on lowering them into a supersaturated solution of alum or of magnesia sulphate, they were proved to be inactive.

But such dried normal crystals were active to a solution of sodic sulphate, even after three days' exposure to the sulphuric acid;* whereas, a solution allowed to evaporate spontaneously on the surface of the tube under cover, forms (modified) crystals, which, as previously related, were found to be inactive. It seems as if the normal crystals become covered with a coating of effloresced anhydrous salt which acts as a protection to the underneath portions, in the same way as oxide of lead does to metallic lead; hence it takes a long time to convert a crystal of the normal salt into the anhydrous by simple exposure to dry air, although it is an exceedingly short operation to perform at temperatures superior to 34° C.

In conclusion, I merely sum up the results of the foregoing experiments.

Any explanation or theoretical considerations are left for a future paper, in which I hope to give the work of other series of experiments now in hand and in projection.

(1.) About 120 experiments were made with thin films, in the manner and with the precautions already detailed, but not a single solution crystallised under their influence.

(2.) Out of 90 odd experiments made with crystals of the normal salt in the manner described, in no single instance did they fail to be active.

London, October, 1870.

EVIDENCE CONCERNING THE GERM THEORY OF FERMENTATION

AFFORDED BY THE ACTION OF CERTAIN SUBSTANCES WHEN
SUSPENDED IN THE AIR.

By ARTHUR ERNEST SANSOM, M.D.

(Concluded from p. 242.)

Expt. 2.—It was intended to examine the influence upon vegetable development when various materials prone to present fungoid organisms were subjected coincidently to the influences of carbolic acid, (a) in the fluid containing the fermentescible matter; (b) in the air alone which was supplied to the materials.

It is necessary to explain that M. Pouchet adduced as evidence, in favour of the theory of spontaneous generation, the development of a peculiar *Aspergillus*, which he himself discovered and named from the circumstances of its formation *Aspergillus primigenius*. Into a flat porcelain dish he poured boiling paste made from wheat-flour, so as to form a layer one centimetre thick. When this began to set he wrote upon its surface with a pencil dipped in a filtered maceration of nut-galls, the words

* At a future day, I hope to have the results of more experiments upon this point."

GENERATIO SPONTANEA. The dish was then covered with a glass plate, and kept at a mean temperature of 24° C. for four days. At the end of that time the words which had been written appeared in bold relief and of a black colour, owing to the growth of an *Aspergillus* bearing black capsules on cylindric non-articulated stems. The reasoning is thus expressed. The germs of this fungus could not have entered with the paste, for this had fully boiled, and experiment shows that the *Aspergillus* spores are totally disorganised by a temperature below that of boiling water; besides, the spores are too large to have escaped direct observation. They could not have entered with the gall-maceration, because this had been filtered, and microscopic examination demonstrated their absence. They could not have entered with the air, or why should they not have covered the whole surface of the paste and not merely those portions which had been moistened by the gall-maceration? It is scarcely necessary to point out how subsequent investigation has invalidated every one of these positions. But the growth of this fungus presents singular advantages for experimental investigation. Its course of development is regular and uncomplicated, and its prominent characters render it very easy to be recognised.

Upon a layer of flour-paste contained in three flat earthen dishes the following solutions are painted in broad bands:—1. Filtered maceration of nut-galls. 2. Brewer's yeast. 3. Syrup of currants. 4. Claret. The surface of one (B) was washed with 5 drachms of a one per cent

FIG. 1.

Aspergillus (seventh day).

In experiment strictly parallel, in atmosphere containing carbolic acid; there was no vegetable growth whatever.

aqueous solution of carbolic acid and then a glass cover was applied. Before a cover was applied to C, a piece of linen imbibing carbolic acid was affixed to it so as to give off the vapour. A, also covered with a glass, was left unchanged.

After two days feathery fungi appeared on the surface of A; B and C remaining, so far as the eye could detect, uninfluenced. On the eighth day the whole were submitted to microscopic examination. The maceration-of-galls band of A presented multitudes of long, jointed filaments bearing on their summits capsules of globular form, containing multitudes of blackish sporules, the *Aspergillus primigenius* of Pouchet. Large spores of the *Aspergillus* were scattered over the whole field, and the capsules were shedding sporules in all directions (see Fig. 1).

The same layer in B (very weak solution of carbolic acid) showed no trace of *Aspergillus*. But it was not destitute of evidence of vegetable organisation and growth. Small spores were seen less than one-fourth the size of those of the *Aspergillus* as well as some penicilliums, mostly short and imperfect, but a few branching.

The same layer in C (vapour of carbolic acid) showed, in nearly its whole extent, no evidence of organisation;

but, at one spot,* there were seen cellular stems branching, and terminating in globular, oval, or truncated apices, the *Aspergillus polymorphus* (see Fig. 2). The other layers in A presented but little special variations. Feathery penicilliums were seen in almost every spot, the area where the wine was applied chiefly being occupied by round white dots, which proved to be aggregations of minute spherical spores. Penicilliums were abundant everywhere—perhaps chiefly on the surface of the red currant syrup. B and C also showed some minute sporules with penicilliums exceedingly less frequent than in A.

The glass covers were now re-applied, but not luted, so that air freely circulated over all the surfaces. In A, growth proceeded with great rapidity. The generation of *Aspergillus* died, and was succeeded by green mould and fine penicilliums. After a few days, maggots appeared.

On the 23rd day, microscopic examination showed in—
A (unchanged): Myriads of sporules; dense bands of penicillium fibres; abundant animalculæ.
B (carbolic acid, 1 per cent solution): A few fibres of penicillium; less frequent minute spores; oval cells (*acetic ferment*).
C (carbolic acid vapour): No spores nor fibres, excepting on the yeast-band, which showed abundant yeast-cells unchanged, and just as when first applied to the surface; no growth whatever.

FIG. 2:

Aspergillus polymorphus. Drawn by aid of camera lucida.

The chief teaching of this experiment, concerning the action of carbolic acid in very weak solution and in vapour, appears to be the following:—

As regards the development of the specific fungus, *Aspergillus primigenius*: Complete prevention in both cases.

As regards the development of the fungoid organisms: Very marked repression, but not complete prevention in all cases.

Comparative action of (1) weak solution of carbolic acid in direct contact with materials for developing fungoid organisms, and (2) carbolic acid present in the air supplied to such materials: The latter by far the more powerful means of repression.

Expt. 3.—The materials were prepared for the development of the *Aspergillus primigenius*, and the measures were repeated with more stringent precautions against the entry of non-carbolised air.

The boiling paste having been poured into a flat dish, two glass covers—the one containing, in its interior, a small quantity of carbolic acid, dropped from crystals melted by heat, and allowed to solidify at the upper part of the glass, the other untouched—were taken; these were then inverted over and imbedded in the paste, and placed aside in a warm place. At the end of six days the results were observed.

Beneath the glass cover containing the carbolic acid (which, of course, could only have acted, by reason of its

volatility, upon the contained air) there was no evidence of any organism whatever. Careful examination showed only minute granules, which aqueous solution of iodine coloured violet, and which were no doubt starch.

Beneath the glass cover containing no carbolic acid, there was exuberant growth of *Aspergillus*, filling up the whole space between paste and glass, its black capsules seen by the thousand, and its spores scattered in all directions.

This was many times repeated with always the same result.

The conclusion may be briefly summarised—

Atmosphere supplied to prepared soil	A, containing no carbolic acid.
	B, containing carbolic acid.
Result	A, abundant vegetation.
	B, no vegetation.

Expt. 4.—It seemed advisable to compare the action upon the air of various volatile media and chemical bodies under precisely similar conditions. The paste and gill-maceration were prepared, and over it, within precisely similar glass covers, the agents hereafter named were suspended. The results are expressed in a tabular form. The order expresses the restrictive power over the appearance of fungoid organisms possessed by the various agents, from the feeblest to the strongest.

Order.	Agent employed.	Appearances on fifth day.	Subsequent appearances, air being admitted.
1.	Air unaltered.	Abundant growth of black capsules, <i>Aspergillus</i> .	<i>Aspergillus</i> completely filled the vessel.
2.	Chloride of lime.	Fibres of penicillium.	This result was unlooked for; for, by an accident, the chloride of lime had actually fallen upon the prepared soil. Yet, in and amongst its particles were developed growing fibres of penicillium.
3.	Sulphurous acid.	—	Soon after exposure to air, abundant and rapid penicillium growth.
	Ammonia.	—	Abundant penicillium growth.
	Ether.	—	Small island of mould appeared, with abundant penicillium; afterwards, a few <i>Aspergilli</i> .
6.	Chloroform.	—	After exposure many days, <i>Aspergilli</i> began slowly to appear.
7.	Camphor.	—	After many days, penicillium slowly developed and gradually covered the surface.
8.	Iodine.	—	—
	Creosote.	—	—
	Phosphorus.	—	—
	Carbolic acid.	—	—

The results of this experiment show that many volatile bodies have the power of preventing the appearance of fungi, when present in the air which surrounds the soil upon which these, under ordinary circumstances, grow luxuriantly. The degree and the persistence of the influence of the various volatile media vary, however, considerably. Some, as ether, sulphurous acid, and ammonia, whilst effectually checking development, while they are actually present in the atmosphere, leave when they are volatilised, or during their volatilisation perhaps, favourable conditions for growth.

Chloroform and camphor leave each a most persistent effect. Some act so persistently that no organism appears at all; that is to say, the paste dries up gradually to a yellowish transparent cake, resembling dry gelatine, and presents no evidence of organisation whatever. For this persistency of effect no agent has been found so powerful as carbolic acid.

There is a further lesson to be learnt from this experi-

* It was probable that the glass cover had not been perfectly luted at this point, consequently the air was imperfectly charged with carbolic acid vapour.

ment. It appears at least to show that the chemical constitution of a volatile medium affords no indication of its energy in preventing the development of fungi. What agent could be expected more profoundly to alter the chemical atmospheric conditions than chloride of lime? Its power as an oxidiser, and collaterally a deoxidiser of aqueous vapour, requires no comment. Yet it was precisely this that was inferior to all the other media, many of which could be shown to exert no perceptible chemical influence in restraining the manifestations of vitality. The observation, however, agrees with that of Hallier, who found mycoderms, vegetating fibres, and oidium forms in the presence of chlorides of the alkalies and alkaline earths.

Expt. 5.—In some of the experiments before recorded the results seem to show that there was less evidence of organisation in a putrescible fluid when a toxic agent was mingled with the air supplied to it, than when the toxic agent was mingled with the fluid itself. This appeared so important as to require further investigation; for it might have a very strong influence in determining the truth between the two theories. For if the doctrine of spontaneous evolution were true, it would, surely, be more probable that the action of any chemical or poisonous agent in repressing the manifestations of life would be most pronounced when mingled with the particles whence vital evolution was proceeding, and least so when only mingled with the atmosphere with which the fluids were in relation. On the other hand, if the germ theory were true, it would be more likely that there would be less fertility when the repressive agent was absent from the fluid and present in the superincumbent air, as the toxic agency would be directly exerted upon the air-germs.

A series of stoppered glass bottles of two ounces capacity was obtained; to the stoppers of some of them were fixed small pieces of sponge. The bottles were then each one-quarter filled with filtered infusion of turnip. Equal quantities of the agents hereafter named were then in the one instance added to the fluid, and in the other dropped upon the sponge so as to become volatilised into the air contained in the bottle. After seventeen days, during which the unmodified infusion of turnip passed through its various stages of putrescence, developing, first, vibrios and bacteria; secondly, fungus spores; thirdly, branching penicillium, which bore abundant fructification, the infusions were examined with the following results:—

Sulphurous acid (1) in the fluid: Abundant vibrios and bacteria in all parts; at the surface innumerable leptothrix chains and fungoid fibres.

Sulphurous acid (2) in the air: Vibrios and bacteria in fluid; on the surface not a trace of a fungoid spore or organism.

Ammonium hydrate (1) in the fluid: Vibrios and bacteria in fluid; on the surface, mass of density-interlacing penicillium, and multitudes of spores.

Ammonium hydrate (2), in the air: Vibrios and bacteria in the fluid; on the surface, no trace of fungoid organism.

It seems difficult to reconcile these results with any other view than with that of the air-containing fungoid spores, which were killed in the presence of a volatile agent which acted as a direct poison upon it. Vibrios and bacteria, whose germs probably exist intermingled with every drop of the liquid, were alike abundant under both conditions, the poisonous agent being too weak to influence them as it was too weak to influence the fungi which developed when the air did not contain the volatile agent.

From the convergence of many methods of investigation and modes of thought, it seems, therefore, that the germ theory presents the strongest claims for acceptance. It suggests that beyond the confines of the visible world there is probably a world of living things almost inconceivably minute, but possessing varying characteristics. Into this world of beings yet unseen it will be the province of science yet to penetrate.

IMPROVED METHOD FOR THE

DIRECT QUANTITATIVE ESTIMATION OF IRON
IN THE STATE OF A PEROXIDE SALT

BY MEANS OF HYPOSULPHITE OF SODA.

By M. A. C. OUDEMANS, jun.

DR. SCHERER was the first to propose the estimation of iron as peroxide, by means of hyposulphite of soda to be added in aqueous solution to the solution of the ferric iron salt until a violet colouration ceased to be produced.* Dr. F. Mohr pointed out that this method was inaccurate, inasmuch as that, at the moment the reaction appeared finished, there was already an excess of the hyposulphite of soda added, which cannot be well estimated, because it is decomposed by the free acid of the iron solution, owing to the absolute necessity of applying heat. MM. Kremer and Landolt tried to remedy this defect by the addition of acetate of soda to the iron solution in hydrochloric acid, the effect of which addition would be the setting free of acetic acid, which does not decompose hyposulphite of soda, and made it possible to estimate any excess of that latter salt, after the reduction of the sesquioxide of iron had taken place, by means of a solution of iodine. By a lucky incident, I have found the means of executing the direct estimation of peroxide of iron, in one and the same operation, without the necessity of previous reduction of the iron; and my method leaves nothing to be desired as regards its accuracy. Before I describe this method, I will pay some attention to the reaction of hyposulphite of soda upon a solution of sesquioxide of iron containing free hydrochloric acid. Hyposulphite of soda is readily decomposed by all mineral acids, even when they are largely diluted; and there is no difference in this respect, whether the acid be poured into the saline solution or the latter into the acid. But, when hydrochloric acid is added to a not too concentrated solution of a persalt of iron, and there is next cautiously added to that solution a solution of hyposulphite of soda, care being taken to avoid an excess of the latter, no sulphurous acid is given off; neither is any sulphur precipitated when the operation is conducted in the cold, since the hyposulphurous acid is, under these conditions, converted into tetrathionic acid—

When some chloride of barium is added to a solution of perchloride of iron thus reduced, it is easy to see that not a trace even of sulphuric acid is formed. It is true that, when the fluid before alluded to is boiled, even if it contains no excess of hyposulphite of soda at all, the free tetrathionic acid is decomposed, and that chloride of barium will detect sulphuric acid; but the ensuing precipitate of sulphate of baryta is, according to my experience, exceedingly small, and out of all proportion with the total quantity of tetrathionic acid. I have, moreover, found that, even when the liquid is cautiously heated, it is not quite possible to obtain a correct estimation of the quantity of peroxide of iron by means of hyposulphite of soda, sulphocyanide of potassium being used as a reagent to indicate the end of the operation; yet the results I obtained were better than I at first expected, being only about from 2-roots to 6-roots too high.

The use of the following method eliminates, I am happy to say, all the defects of this method, which thus becomes available for the correct, ready, and easy estimation of the peroxide of iron in an acid solution:—I add to the iron solution, which may even contain a goodly excess of free chlorhydric acid, one or two drops of a solution of any salt of oxide of copper, and, next, as much of a solution of sulphocyanide of potassium as will suffice for imparting to the iron solution a deep red colour (for this purpose, I take from 2 to 5 c.c. of a solution of this salt at 1 per cent). I next pour from the burette the solution of hyposulphite of soda, whereby it will be seen that the well-known violet

* *Zeitschr. f. Anal. Chem.*, vol. i., p. 214.

colouration which ensues temporarily when solutions of pure iron and hyposulphite of soda come into contact does not, in this instance, make its appearance; but the red colouration, due to the sulphocyanide, gradually fades away by the addition of the hyposulphite (this decolouration is especially very marked where the liquids meet each other.) At first, the addition of the hyposulphite of soda solution may be made freely; but, when a certain quantity of that fluid has been added (care being taken to stir the iron solution well), it is necessary to add the hyposulphite drop by drop, and to wait a few seconds before a drop more is added. With a little practice, the operator soon learns when the end of the operation is about to be reached. At last, the liquid becomes as colourless as pure water, provided not too much of the copper solution has been added. The iron solution may be heated to 40°, not only without any danger, but with the decided advantage of accelerating the reaction, especially towards the end of the operation, which, however, whether heat be applied or not, can be performed in a few minutes.

The copper salt is to be considered as the cause of the reduction of the iron, it being my opinion that the reducing action of the hyposulphite of soda is first exercised upon the salt of copper, which, in its turn, reacts upon the iron salt; and the former appears to undergo, alternately, reduction and oxidation, and thus to aid the reaction and to play a somewhat catalytic part. The quantity of copper salt required is very small indeed, because I have seen even that so small a quantity as $\frac{1}{4}$ of a milligram of crystallised sulphate of copper exerts a marked effect; I also found that other substances, among them nitric acid, exert an analogous action, but also disturb the regularity of the process. When the iron solution has become quite colourless, the cupric salt is, in its turn, permanently reduced to a cuprous salt; and, if the cupric salt were not added in too small quantity, there is, after awhile, a whitish precipitate of subsulphocyanide of copper formed. I am not aware (and, therefore, call attention to this *en passant*) whether anyone has pointed out how the reduction of cupric to cuprous salts is brought about by hyposulphite of soda. My experience has taught me that, by this reduction, tetrathionic acid is also formed; and if I admit, as is done by most chemists, the formation of a double hyposulphite of soda and of suboxide of copper, this reaction may be formulated as follows:—

Returning to our subject, I state, in the first place, that my large experience has proved to me that the use of the sulphocyanide of potassium as an indicator is, notwithstanding all that has been alleged against its use in this process by M. Mohr, perfectly safe, and not in the least inconvenient. As regards the concentration of the iron solution and the quantity of free acid, the operator has a great latitude in this mode of operation, but it will be clear that too great excesses are to be avoided. As regards the accuracy of this method, I shall communicate some results, but desire to observe, first, yet, that the estimation of iron by this method is not interfered with by the presence of the salts of alkalis, strontian, lime, magnesia, protoxide of manganese, and alumina; neither do the salts of nickel, cobalt, or copper interfere, provided they are not present in so large a quantity as to become a hindrance by the colours they might impart to the iron solution. The test solution of hyposulphite of soda (at 1-10th of normal standard) I prepared by dissolving 24.8 grms. of the perfectly pure salt in 1 litre of water, taking care to test this solution repeatedly with re-sublimed iodine. I also dissolved 24.1 grms. of iron and ammonia-alum in 500 c.c. of water, and added some c.c. of concentrated hydrochloric acid. Each c.c. of this solution ought to correspond to 1 c.c. of the solution of hyposulphite of soda. I found—

Iron solution.	$\text{S}_2\text{O}_3\text{Na}_2$.	Iron solution.	$\text{S}_2\text{O}_3\text{Na}_2$.
10 c.c. =	10.0 c.c.	100 c.c. =	100.50 c.c.
40 " =	40.0 " "	25 " =	24.95 " "
20 " =	19.9 " "	25 " =	25.00 " "

I dissolved 5.6168 grms. of fine piano iron wire in hydrochloric acid, to which some chlorate of potassa was added; the liquid was boiled a sufficiently long time to decompose any excess of chlorate which might be present, and the bulk of the liquid was next brought to 2 litres. Taking for granted that the metal employed contained 99.7 per cent of pure iron, 2 c.c. of the solution ought to correspond to 1 c.c. of the hyposulphite solution. I found—

Iron solution.	$\text{S}_2\text{O}_3\text{Na}_2$.
20 c.c. =	10.00 c.c.
40 " =	20.05 " "
60 " =	29.95 " "
100 " =	50.10 " "
200 " =	100.05 " "

The following experiments were made so as to preclude any preconceived notion about the quantity of iron taken for experiment, care being taken to estimate the quantity of iron only after the end of the assays with the hyposulphite:—3.576 grms. of iron and ammonia-alum were dissolved in water, some hydrochloric acid added, and the solution made up to 300 c.c.; the average result of three assays was, that the quantity of iron, Fe_2O_3 , found was 0.5932, and the quantity calculated 0.5934. In another experiment of the same kind, with 4.0200 grms. of the same salt, also made up to 300 c.c. solution, the quantity of iron found was 0.6656, and the calculated quantity 0.6672. 2.6055 grms. of the same salt, treated as above mentioned, and made up to a solution of 250 c.c., gave, as result, 0.4300 of Fe_2O_3 found, and 0.4325 of the same calculated. 0.4980 grms. of fine piano-wire were dissolved as already stated, in chlorhydric acid, and the liquid made up to 300 c.c. 100 c.c. of this solution required, for three assays, respectively, 29.8, 29.6, and 29.6 c.c. $\text{S}_2\text{O}_3\text{Na}_2$; the quantity of iron, Fe, found amounted, on average of the three experiments, to 0.4985, while the quantity calculated (taking the wire to contain 99.7 per cent of metal) amounts to 0.4965.

Influence of the Degree of Dilution.—25 c.c. of standard solution of Fe_2Cl_6 at 1-10th normal required 25 c.c. $\text{S}_2\text{O}_3\text{Na}_2$ at 1-10th normal; 25 c.c. of the same solution of iron, diluted with 50 c.c. of water, required 25.05 c.c. of the same hyposulphite solution; 10 c.c. of the iron and 100 c.c. of water required 10.0 c.c. of the hyposulphite solution. (Under these conditions, the experiments require more time.) In order to test whether a more concentrated solution presented any difficulties, the following experiments were made:—I dissolved 0.1953 grms. of piano-wire in hydrochloric acid, added chlorate of potassa, well acidified the fluid, boiled, and made up with water to 20 c.c. I next added the hyposulphite standard solution, of which I used 34.9 c.c., giving as result, Fe—found, 0.1946; calculated (at 99.7 per cent, as above), 0.1954. 3.3680 grms. of sulphate of iron and ammonia (ammonia-alum) were dissolved in a small quantity of water, and the iron oxidised with chlorate of potassa; HCl was next added in excess, and the liquid boiled, and afterwards made up to 150 c.c. The quantity of standard hyposulphite solution required was 85.7 c.c. iron, Fe—found, 0.4799; calculated, 0.4811.

Influence of the Free Hydrochloric Acid.—25 c.c. of the Fe_2Cl_6 standard solution at 1-10th normal and 1 c.c. of strong HCl required 25.0 c.c. $\text{S}_2\text{O}_3\text{Na}_2$.

Same iron solution.	Strong HCl.	Hyposulphite solution (standard).

25 "	15	26.5

[NOTE.—We must not neglect to state here that, according to M. O. Popp (*Zeitschrift für Chemie von*

Beilstein, No. 11, 1870), the addition of a few drops of a solution of a salt of copper, as directed by the author of the paper above mentioned, is unnecessary, M. Popp having found that the reaction and operation succeed perfectly if the iron solution is heated to 40° without any addition of a salt of copper.—Ed. C. N.]

ON FERMENTATION.*

By Professor A. W. WILLIAMSON F.R.S.

(Continued from p. 248).

LECTURE I.

I OUGHT, however, in justice to the wonderful process which I alluded to, to give you two or three other particulars regarding it. I showed that sugar is broken up by the ferment into these products, but no case is known of pure sugar—and when I say pure sugar, I mean sugar in the purest form in which we have it—being decomposed by yeast. If you were to put some ready-made yeast—thriving, growing, yeast—into a solution of chemically pure sugar, some of your yeast would decompose, some of it would resolve itself into other products, and other parts of it would be absorbing those products which are present in the liquid, and whenever the process is to be carried on advantageously and rapidly, it is customary to add some saccharine liquid—some other substance capable of nourishing the yeast. When I want good fermentation I do not take water to dissolve my sugar, and put yeast into it, but I boil some of this malt, which is one of the best materials for the purpose, in water, and take a decoction of malt, or decoction of yeast, and put the sugar into it. In such a liquid there are several bodies which we know; and I may safely say that there are a great many others which we do not know, and there is no doubt that their presence is of considerable importance to the chemical change which takes place. There are substances which I shall presently have occasion to show you and to speak of, formed by the germination of the grain, by the formation of the malt, which are related somewhat to this body which I have here. This was some pure wheat flour—very kind of flour would not do—and it is supposed that some people mix other materials with flour. It was kneaded up with water, pressed together, and, whilst the pressure was being continued, water was allowed to trickle over it. I have in another bottle some of the water that flowed over it. There is a white substance deposited from this water, which is commonly known and much used by the name of starch, and starch is, in its chemical composition, first cousin to sugar; it is a substance which passes over very readily into a kind of sugar by a process I shall presently have occasion to allude to. But the little ball of flour while being kneaded had the starch washed away from it, and I have left, as the result, a substance which is commonly known by the name of gluten. If I were to describe it in chemical language, I should say it is something like flesh, or the muscular fibre of animals, for, in chemical composition, it approaches very nearly to that. When barley is malted, and kept in a warm place for some time, the grains begin to germinate and decompose, and some bodies are formed from this gluten, which is partially broken up. The malt contains also some sugar made from that starch—grape sugar, as we usually call it.

If we had only those extreme cases, I really do not know what we should do. If we had in our science one set of bodies which appeared so constantly to act at variance with the general laws which the others obey, I think we could not call chemistry a science. I have taken two or three examples to show you the definite proportions which we find to regulate the ordinary process of combination. I might have taken thousands, but the

point is that this law does not appear to apply at all to these chemical changes which we call fermentation. One of the active substances in fermentation is being formed, it is increasing, not disappearing at all, and the contradiction is so strong and manifest that the only way out of the difficulty will be to do something of the kind which I was speaking of some time ago, that is to say, see if we cannot get some intermediate facts which will serve to connect the extreme ones; to see if we cannot get at first something between the two classes, and then try to get some further links between them. There are processes of chemical change—I will not call them processes of fermentation, for I do not know whether they are, but which are analogous to it, and some of them are very interesting and very beautiful. I have here a substance called amygdalin, made from bitter almonds. It is a bitter tasting substance, and consists of four elements which it is not necessary that I should name. In this other bottle I have a paste formed of sweet almonds, which have been crushed with a pestle and mortar, and I will put some of it into the warm distilled water in this flask. Into the mixture I will put some of this amygdalin. If I were to leave it without that addition, there would be very little change; the substance would gradually subside, but there would be no product given off in the way you will presently see. After letting it stand for a few minutes, I will pour some of the mixture into an open vessel, and we shall be able, without difficulty, to perceive a fragrant smell, which is due to the presence of a liquid of which I have a quantity here, a substance known by the name of oil of bitter almonds. If we were to perform the same experiment on a large scale, and macerate some of this amygdalin with almond paste, put them together with warm water, distil the mixture, and collect what comes over, we should find that water would pass over, and with it would be a few drops of oil of bitter almonds, and the amygdalin would be decomposed in the process. There is in the sweet almond paste a substance which I cannot describe in better terms than by comparing it to that gluten which I showed you just now. It is very similar to it in its composition, and by the contact of this, the synaptase, as it is called, with the amygdalin the elements of the amygdalin are broken up into several products; one of them is the oil of bitter almonds, another is prussic acid, which generally accompanies the oil, the third is a variety of sugar of the kind which is called grape-sugar, and there is probably also some formic acid. Here we have the breaking up of a complex body, amygdalin, into several simpler bodies by the action of the body called synaptase; but there is not in the process, as far as I know, any living organism at work. There is a substance which is somewhat similar to these living organisms, but there is no organised structure, as far as our knowledge goes at present.

Take another experiment. I have here something which is not a *blanc mange*, although it looks something like it; it was made by boiling potato starch with water. We let it cool, and then turned it out; some was put into a flask with two or three ounces of crushed malt. It was warmed to a temperature of 60° C. for about an hour; there was no boiling. The substance was then squeezed through a cloth to keep back the husks of the malt, and here is the liquid which ran through. It is perfectly liquid, and its consistency is entirely different from that of starch, from which it was made; it is quite sweet to the taste, and there is a large quantity of sugar in it. There is also another body which we class with the sugars; that is, there is in this liquid a good deal of a kind of gum, which we call dextrine, which would easily pass into sugar. The starch, when it was being converted by the action of the malt into those soluble bodies, did no, so far as we know, break up into simpler substances; the process was of a different kind. It assimilated the water—the starch combined with the water, and at the same time divided itself, some of it forming one and some the other product. Here, also, there was not, as far as my know-

* The Cantor Lectures. Delivered before the Society of Arts.

ledge goes, any ferment, or any organised cells in the liquid. If they were present it was an accident, and was not essential to the change which took place. I am the more confident in saying that no ferment was there present, for we can get, and we very often do get, precisely the same formation of starch without any malt at all. If, instead of warming some of that starch with the infusion of malt, I had mixed it with a little—about 5 per cent—of that strong sulphuric acid, and had heated it, it would have been dissolved almost like sugar in water. In fact, there are now in Germany, and also in England, manufactories in which starch is converted by the action of dilute sulphuric acid, into grape-sugar, and the same change which we get by organic substances—that is the point—we also get by the action of this mineral acid.

Another change of the same kind I may mention, especially as the subject of it is in itself interesting. I have here a substance which people have been accused of making for the purpose of adulterating quinine. It is made from willow bark, and is believed to possess febrifuge qualities, so that there was some little excuse for what I have mentioned. This substance is called salicine, and when heated with dilute sulphuric acid, in the same way as the starch when so heated, was converted into sugar and dextrine; this salicine breaks up in a way which I might compare with that in which some bodies are broken up by fermentation.

Another case of same kind is afforded by tannin, a substance extracted from gall nuts, and which is present in oak and many other barks. It is used for combining with gelatine, which is the principal constituent in hides, to form leather. If we dissolve this tannin in water, and leave it in an open vessel, it will get mouldy; and if you examined it a some time you would find none of it left. It would all disappear, just like sugar in the process of fermentation, and in place of it you would find, in that particular process, a body which you might easily crystallise out from the liquid, and which I have here; it is called gallic acid. It is a body resembling tannin in some respects, for instance, in the property of forming, in combination with iron, a dark substance, which is used in suspension in water, for writing ink. But it will not do to form leather in combination with gelatine. If you left the tannin in an open vessel, it would decompose, and there would be left gallic acid, and some other material which was formed at the same time would have disappeared. By boiling tannin with dilute acid, we get the process performed more regularly. Upon boiling some tannin with dilute sulphuric acid, you would find that water would be taken up by it, the tannin would combine with water, and it would break up into sugar and gallic acid, the process being exactly like that which I mentioned in the case of salicine. There is a most direct analogy between the process of breaking up which sulphuric acid effects upon tannin and that of fermentation. I ought to say, when telling you of the decomposition of the tannin, that it is effected by little animal organisms present in the liquid, and it appears that they are the agents of the transformation.

(To be continued).

ON THE PRECIPITATION OF ANTIMONOUS SULPHIDE FROM BOILING SOLUTIONS.

By STEPHEN P. SHARPLES.

In the precipitation of antimonous sulphide, I have found it of very great advantage to employ the following process:—Into the solution, containing, as usual, tartaric and free chlorhydric acid, a current of sulphydric acid gas is to be passed, the liquid being, during the passage of the gas, gradually heated to the boiling-point. The boiling is then to be continued for fifteen or twenty minutes, the current

of gas passing uninterruptedly until the voluminous sulphide has become a dense granular powder occupying but a small portion of the original volume of the sulphide. The sulphide may then be washed with great facility, and dried upon a sand filter at 200°—300° C. All the determinations of antimony made in the laboratory of the Lawrence Scientific School for some years have been executed in this manner, the results leaving nothing to be desired. Arsenious sulphide does not become granular and dense under the same circumstances. In this connection, I may be permitted to mention that the sulphides of nickel and cobalt, when precipitated from boiling solutions in the manner recommended by Professor Gibbs some years since, should be filtered off, and washed immediately after precipitation. In this manner, there is no oxidation upon the filter, even during the drying of the precipitate. But, if the sulphides are allowed to stand in the solution from which they have been precipitated, for even a few hours, they will usually oxidise upon the filter during the washing.—*American Journal of Science.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 17th, 1870.

Professor WILLIAMSON, F.R.S., President, in the Chair.

THE following papers were read:—

"*Mineralogical Notices*," by Prof. MASKELYNE and Dr. FLIGHT. The contents of this communication were:—

1. *On the Formation of Basic Cupric Sulphate.*—In 1867, M. Pisani described a mineral which he supposed to be the Woodwardite of Mr. Church. The substance, however, is not the latter mineral. It had previously been examined in the Laboratory of the British Museum, and the results sufficiently tallied with those of M. Pisani to identify the mineral. It can be divided into an inner layer and an outer crust. The first consists of—

Copper oxide	24.561
Alumina	23.063
Calcium oxide	0.086
Magnesium oxide	0.749
Sulphuric anhydride	6.775
Silicic anhydride	6.689
Water	38.528

100.451

The crust is thus composed—

Copper oxide	10.255
Alumina	27.250
Calcium oxide	1.403
Magnesium oxide	6.183
Sodium oxide	0.643
Sulphuric anhydride	2.438
Silicic anhydride	7.530
Carbonic anhydride	0.528
Water	43.969

100.199

These numbers give us but little insight into the constitution of the mixed minerals. The only interest they offer is in the light they seem to throw on the possible modes of the formation of native basic cupric sulphates. The actions of solutions of magnesium or calcium sulphate on malachite may terminate in the production of Langite. An experiment in the Laboratory showed that an insoluble cupric sulphate and acid magnesium carbonate were actually formed.

2. *Opal from Waddella Plain, Abyssinia.*—Mr. Markham presented to the British Museum some remarkable speci-

mens of green opal from the above locality. Its analysis yielded the following numbers:—

Silicic acid (soluble)	90.562
Silicic acid (insoluble)	2.049
Water	5.656
Iron peroxide	0.933
Manganese peroxide	trace
Calcium oxide	0.137
Magnesium oxide	0.311

100.648

3. *Franconite, Cornwall*.—Its analytical numbers point to the formula—

It is, in fact, a fluor-apatite in which one equivalent in every six of the calcium phosphate is replaced by carbonate. The crystallography of this mineral seems also to point to its not being ordinary apatite, and, in fact, to its not being the same mineral as the original *Franconite* from *Wheal Franco*.

4. *Epidote and Serpentine, Iona*.—A pebble, in which a green mineral traverses bright red felspar and quartz in veins, was sent by the Duke of Argyll to the British Museum. Its analysis leads to the view that it consists of a lime epidote with some 23 per cent of quartz, the former mineral having the following constitution:—

Two specimens of serpentine, of the same locality, gave the general formula—

where R represents, in one case, Mg with a little Fe and Ca; in the other, Mg with nearly one-fifth of its equivalent of an equal mixture of Fe and Mg.

5. *Vivianite*.—Two kinds of this mineral were found in an unknown Cornish locality. The one, of a pale blueish tint was ascertained to consist of—

Iron protoxide	42.709
Iron peroxide	1.126
Phosphoric anhydride	28.526
Water	28.984

101.345

The other variety, of a brownish colour, gave on analysis—

Iron protoxide	42.889
Iron peroxide	0.801
Phosphoric anhydride	28.792
Water	29.433

101.915

Both proved, therefore, to be octahydrated ferrous orthophosphate, $3\text{FeO} \cdot \text{P}_2\text{O}_5 \cdot 8\text{H}_2\text{O}$, and the difference in the colours can only be ascribed to some minute difference in the degree of oxidation of the iron. The brown variety was enclosed in nodules of a dark blue earthy mass which was composed of:—

Iron protoxide	37.214
Iron peroxide	9.169
Phosphoric anhydride	23.897
Carbonic anhydride	5.162
Water	23.871
Silica	0.811
Organic matter	0.826

100.920

These numbers may be interpreted as representing 5 equivalents of octahydrated ferrous orthophosphate with 1 equivalent of octahydrated diferric phosphate, mixed with four equivalents of ferrous carbonate. The British Museum possesses some fine crystals of *vivianite* from *Fernando Po*, the chemical examination of which gave as results:

Iron protoxide	38.501
Iron peroxide	5.083
Phosphoric anhydride	27.802
Water	28.326

99.712

This specimen stands intermediate between the blue and brown crystalline varieties on the one hand, and the blue earthy mineral on the other.

6. *Cronstedtite*.—The analysis of this mineral presented considerable difficulties, inasmuch as it was extremely difficult to free it from the substances associated with which it is found.

The *cronstedtite* in question possesses an unusual interest from a crystallographical point of view, being one of the best defined types of hemimorphism.

7. *Pholerite*.—This mineral, derived from India, is of a pale flesh-white, penetrated in several places by patches and veins of a black mineral. An analysis of the flesh-white mineral gave the following results:—

Silicic acid	43.144
Aluminium oxide	41.073
Water	15.783

100.000

Traces of iron and manganese oxides accompany the alumina. A new name was proposed for this mineral, but the analysis shows it to be nothing but *pholerite*.

MR. CHURCH observed that it was a matter of congratulation to have those beautiful specimens, which are stored in our magnificent national collections, investigated in so excellent a manner as the contents of the paper just read had shown.

The next communication was a note by MR. CHAPMAN, "On the Oxides of Nitrogen."

In a paper read at the last meeting of the Chemical Society, Mr Chapman mentioned that he had quantitatively estimated nitric oxide by converting it into nitric acid and determining the latter by the production and weighing of the baryta salt. Objections were then raised as to the possibility of the completeness of such a conversion. Mr. Chapman now endeavoured to show, by referring to well-known chemical facts, that, whether N_2O_3 , N_2O_4 , or N_2O_5 be formed when NO is left with excess of oxygen over water, the final result must be the transformation into nitric acid. He, moreover, referred to the circumstance that the above-mentioned facts were accepted by Schloesing, by Playfair, and Wanklyn, as sufficient to found upon them the quantitative estimation of nitric acid. As to SO_2 being present in his experiments, Mr. Chapman found this by special researches to be of no consequence.

MR. HARCOURT reasserted that, on his passing nitric oxide into oxygen, he obtained, as result, nitric peroxide; when reversing this order, and passing oxygen into nitric oxide, a mixture of N_2O_4 and N_2O_3 seems to be formed.

Mr Chapman replied that the different results obtained by Mr. Harcourt and by himself were, in all probability, due to differences of the temperatures at which the respective experiments had been executed.

PROFESSOR WILLIAMSON took occasion of this repeated mentioning of nitric peroxide to remark that this compound may be viewed as

i.e., as water in which the one hydrogen was replaced by NO, the other by NO_2 .

The Society then adjourned to December 1st, when Mr. Perkin will read a paper "On some Derivatives of Anthracene."

GLASGOW PHILOSOPHICAL SOCIETY:
(CHEMICAL SECTION).

The annual general meeting was held in the Society's rooms, Corporation Buildings, on Monday evening, the

21st inst., at eight o'clock. Mr. W. R. Hutton, Vice-President, in the chair.

Dr. Wallace, F.R.S.E., F.C.S., was unanimously elected President for three years, in room of Professor Anderson, whose term of office has expired.

Mr. John Ferguson, M.A. was appointed a Vice-President in room of Dr. Wallace.

Four new members of Council were elected in place of the four who retired by rotation.

The following is the present list of office-bearers:—

President—Dr. Wallace, F.R.S.E., F.C.S.

Vice-Presidents—Mr. Alexr. Whitelaw; Mr. W. R. Hutton; Mr. John Ferguson, M.A.

Members of Council—Mr. James Anderson; Dr. John Clarke; Mr. James Couper; Mr. John Ferguson, M.A.; Mr. W. R. Hutton; Mr. James Macfear, F.C.S.; Mr. P. M. Moir; Mr. T. L. Patterson, F.C.S.; Mr. E. C. C. Stanford, F.C.S.; Mr. John Sutherland; Mr. R. R. Tatlock, F.R.S.E., F.C.S., Secretary; Mr. Alexr. Whitelaw.

ROYAL IRISH ACADEMY.

THERE was a general meeting of this Society on Monday, the 14th, when the following papers were read:—

I. REV. MAXWELL CLOSE, "On M. Delaunay's Views Relative to the Condition of the Interior of the Earth."

II. SAMUEL FERGUSON, LL.D., "On the Difficulties Attendant on the Transcription of Ogham Legends, and the means of avoiding them."

The following recommendation of the Council was also adopted:—

"That Her Majesty's Government be memorialised to use their good offices in order to prevent, as far as possible, any injury during the present siege to the collections in Paris, which are universally acknowledged to be of inestimable value to Science, Literature, and Art."

LABORATORY NOTES.

SUB-PERMANENT MAGNETISM EXPERIMENT.

THE following experiment may be interesting or useful to some of your readers. The object of the experiment is to produce, in a few minutes, what Dr. Tyndall has named sub-permanent magnetism; and thus represent to a class quickly what is effected by the earth slowly in soft iron lying in the magnetic meridian, and subject to molecular disturbance from percussion or other causes.

The requisites for the experiment are—a block of cast-iron (wrought-iron might, perhaps, do) slightly magnetised, a bit of soft iron wire, a hammer, and a magnetic needle for testing the wire.

Expt. 1.—Lay the iron wire on the block, and hammer it lightly from end to end, for a few seconds. Presented to the needle, the wire will be found magnetised, showing distinctly strong N. and S. poles, produced by the S. and N. poles of the block.

Expt. 2.—Place the wire reversed on the block, i.e., lay the N. pole of the wire on the N. pole of the block, and hammer as before. Tested again by the needle, the wire exhibits its poles reversed.

Expt. 3.—Lay the wire as in Expt. 1, and hammer; the original polarity is restored. Finally, by changing the position of the wire, the pole may be changed and re-changed as long as the wire lasts.

This experiment would seem to represent well the magnetising action of the earth. The block personates the earth with its magnetism, which is not less comparatively than that of the cast-iron. Were the wire to remain for a considerable time lying on the block, it would be magnetised. The hammering effects quickly, in the whole

wire that molecular disturbance which is slowly and piece by piece produced in great masses of iron standing on the earth.—I am, &c.,

E. KERNAN.

Clongowes.

CORRESPONDENCE.

ATACAMITE.

To the Editor of the Chemical News.

SIR,—Under the head of "Notes and Queries," in your last week's impression, atacamite is mentioned as a "rare mineral; new to Britain." This is an oversight, as you will be quite well aware that it has long been found at St. Just, Cornwall, and that its variety, Botallackite, is only known as a product of the Botallack mine in that county.—I am, &c.,

THOS. C. ARCHER.

Edinburgh Museum of Science and Art,
Nov. 22nd, 1870.

THE RECENT DISCUSSION AT THE CHEMICAL SOCIETY.

To the Editor of the Chemical News.

SIR,—Although there was no doubt that nitric oxide in presence of an excess of oxygen, and of much water, and at moderate temperatures, passes totally into nitric acid, still, the recent discussion at the Chemical Society is hardly to be regretted. If it did not throw any light upon the scientific question—if the fact of such a change taking place was manifest to any one who consulted the common chemical text-books, and still more patent to those who had experimented for themselves—it, at any rate, was calculated to illustrate the curious incompleteness of our chemical education; or, perhaps, I ought to say, it illustrates the necessity of investigating some of the commonest and most elementary of chemical facts that have, somehow or other, been lost sight of.

In my eyes, criticism is one of the paramount needs of chemistry. One false fact, stubbornly maintained, is capable of closing the way to those generalisations which are the glory of science, and the sweeping away of one such false fact is, usually, a far greater service than the correct observation of a new one.—I am, &c.,

J. ALFRED WANKLYN.

PURIFICATION OF SYRUPS.

To the Editor of the Chemical News.

SIR,—I regret to have to trouble you with the following remarks, but I consider it a duty to do so.

You have published, in the last number of your interesting and valuable journal, a notice on a patent, taken by Dr. Seyferth, for the purification of syrups and molasses in the manufacture of sugar by a sulphurous acid solution.

I beg to state that I carried out the application of this acid in sugar refining so far back as 1850, and sold it to some sugar refiners, who employed it successfully to my knowledge, and no doubt are doing so at the present time.

Dr. Seyferth will find a notice of my process in the *Technologiste*, vol. xix., p. 478 (1858), and in the *Chemist*, vol. v., p. 344 (1858). There, it is stated that the application of sulphurous acid possesses two marked advantages for the sugar refiner—(1) "That it stops the fermentation of his hot liquors as they come out of the char-filters; and (2), when properly applied, it tends to prevent the

re-colouration of the liquors during their concentration in the vacuum-pan. In practice, I found that very successful results were obtained by adding 2 gallons of a saturated solution of sulphurous acid to 100 gallons of decolourised liquor as it left the char-filter, and was collected in tanks until pumped up or run into the vacuum-pan.

In the same volume (same page), I also described a very simple and cheap mode of preparing hundreds of gallons (per day) of sulphurous acid.—I am, &c.,

F. CRACE CALVERT.

Royal Institution, Manchester.

MISCELLANEOUS.

Royal Institution of Great Britain.—The courses of lectures before Easter include eleven lectures by Dr. Odling, F.R.S., on "Davy's Discoveries in Chemistry;" four lectures by W. H. Channing "On the Progress of Civilisation;" three lectures by Professor Jowett, M.A., "On Socrates," and four lectures by H. O'Neill, R.A., "On the Spirit of the Age." Friday evening discourses, which commence on January 20th, 1871, are expected from Dr. Tyndall, Dr. Odling, Mr. E. J. Reed, Mr. James N. Douglass, Dr. Carpenter, Captain Noble, Professor Clerk Maxwell, Mr. J. N. Lockyer, Mr. W. Mattieu Williams, and Professor Max Müller.

Pernanganate of Potassa against Coryza.—Although not exactly belonging to the subject matter usually treated in this paper, we think we may briefly call attention to the use of permanganate of potassa in very dilute solution (0.18 grms. = 1.67 grains to 60 grms. or c.c. = to about 2 fluid ounces) against coryza, cold in the head, attended with severe sneezing. Of the permanganate solution, some 20 to 60 drops are poured into a tumbler-full of water, and of this liquid every two hours a quantity of a table-spoonful is snuffed up the nostrils, and if there be any soreness of the throat, the same liquid is applied as a gargle. Dr. Franck, of Munich, states that he has prescribed this mode of treatment now for some years, and found it very efficient by curing the complaint in about from two to four days.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, September, 1870.

This number contains the following original papers and memoirs:—

Chemical Assay of Cements.—Dr. C. Bender.—This memoir has been written with the view of enabling parties somewhat acquainted with chemistry, but not professional chemists, to perform an analysis of cements—viz., so-called Portland and Roman cements. As an introduction, the paper gives a lengthy description of the physical qualities of cements; but it is clear (except that Portland cement of good quality exhibits, when seen under the microscope, a foliated structure, and that a yellowish brown colour is an indication of adulteration), that the outward aspect, specific gravity, and other properties of these substances must of necessity vary with the mode and materials of preparation. The chemical analysis is conducted in the following manner:—A quantity of from 1 to 3 or 5 grms. (according to the author, the quantity to be taken depends upon the accuracy of the balance the operator has at hand; but it is understood, at the same time, that the balance should be capable of turning, when loaded in each pan with 30 grms., with at least 1–2 milligrams.) is weighed off, and the hygroscopic water estimated by drying in an air-bath at

180°–200°. The water of constitution, and also the carbonic acid, are estimated by fusing another portion of the cement in a platinum crucible along with about four times its weight of previously fused and pulverised borax; the joint quantity of both these constituents, exclusive of the hygroscopic water, will not, on an average, exceed 3 per cent. For the estimation of the other constituents, a quantity of from 4 to 6 grms. is weighed off, and, after having been put into a beaker, hydrochloric acid, of about 1 104 sp. gr. at 15°, containing 20 per cent of anhydrous acid, and boiling at 110°, is added, and the vessel and contents first heated on a water-bath, and next evaporated to dryness. After the dry residue has been moistened with hydrochloric acid, it is left standing for twelve hours, water added, and filtered off, the residue on the filter being pure silica if the cement is well made. The filtrate and washings are diluted with distilled water to 1000 c.c.; and, of these, 300 c.c. are taken for the estimation of the alumina, oxide of iron, lime, and magnesia. For this purpose, the acid liquid is, first, as near as possible, neutralised with a solution of carbonate of soda; next, a solution of acetate of soda is added, and the liquid boiled, whereby basic acetate of iron and alumina and (in case phosphoric acid were present) phosphate of peroxide of iron are precipitated. This precipitate is collected on a filter, and, after having been washed, dried, ignited, and weighed, the estimation of the other constituents of the cement—viz., phosphoric and sulphuric acids, manganese, lime, magnesia, alkalies, and chlorine, is done by methods fully described in all works on quantitative chemical analysis; but, in addition to the process here alluded to, it is necessary to disintegrate and fuse, by well-known methods, a separately weighed portion with pure carbonate of soda.

Meteoric Dust among Snow.—Dr. A. Husemann.—This paper gives an account of a reddish coloured dust which fell along with snow in the Swiss canton Du Vaud in the winter of 1867. According to a calculation, made from experiments and observations conducted with care, the quantity of dust fallen over the entire surface of the canton amounted to about 1500 tons. The author examined the dust, as well as the snow which had fallen simultaneously. The water yielded by the snow contained a considerable quantity of sulphate of lime and organic matter, both of which are absent in ordinary snow-water, at least in Switzerland. The microscopical inspection of the dust proved it to contain minute particles of mica, felspar, quartz, and variously-shaped organic matter. After having been dried at 100°, and ignited, the loss amounted to from 20.8 to even 24 per cent for four different assays. The greater portion of this loss was due to the volatilisation of water of crystallisation and constitution, but nitrogenous organic matter was also found to be present. Of the residue after ignition, about half was found to be soluble in hydrochloric acid. This solution, which was only qualitatively tested, contained peroxide of iron, lime, alumina, magnesia, and sulphuric acid; the portion insoluble in acid, having been fused with a mixture of potassa and soda, was found to contain, beside a large quantity of silica, also alumina, oxide of iron, and lime. The dust, when treated with an acid, gave off carbonic acid largely. The author also quotes an analysis of so-called Orandust—that is to say, a dust carried across the Mediterranean to Europe, that dust being undoubtedly brought by wind from the Sahara Desert. The author found this dust to contain, in 100 parts—Silica, 54.85; carbonate of lime, 20.48; sulphate of lime, 0.41; carbonate of magnesia, 3.95; peroxide of iron, 4.25; alumina, 0.98; water, 2.34; organic matter, 3.90; chloride of sodium, traces. The author observes that this analysis is not complete, being short from 100 by about 8 per cent, this being due to the very small quantity of substance at the disposal of the operator.

Morphia from the Capita Papaveris Albi.—Dr. Vorwerk.—The author states that he has for some time past prepared morphia with good success from the almost valueless poppy-heads, which, when first exhausted with water, yield from the extract about 3–10ths per cent of the heads of morphia.

Alkaloids in Plants belonging to the Family of the Boraginæ.—Dr. Buchheim.—The author briefly states that, having found it stated that the extract of cynoglossum acts as a poison, in a manner similar to the American arrow poison, known as *cucurara*, he felt induced to try to extract, from various plants belonging to the family above named, an alkaloid. In this respect, he was only partially successful, by obtaining from the cynoglossum a body which, although not quite pure, exhibited properties which—as, for instance, alkaline reaction, precipitation by tannin, by phospho-molybdic acid, and chloride of mercury—proved it to be a compound akin to an organic alkaloid. This substance, for which the name of cynoglossine is proposed, was found to have a specific poisonous action on various animals.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 8, 1870.

This number only contains the following paper relating to physico-chemical and allied sciences:—

Researches on the Constitution of Phloretic Acid and on Sulpho-Hydrocinnamic Acid.—L. L. de Koninck.—In the first portion of this essay the author gives an account of his researches made for the purpose of verifying, experimentally, the hypothesis of MM. Glaser and Buchanan, who view phloretic acid as being normal ortho-oxyphenyl-propionic acid; but the author's experiments have not led to any direct result in this direction. The second part of this paper treats on sulpho-hydrocinnamic acid, which is prepared by dissolving hydrocinnamic acid in a mixture of strong sulphuric and fuming sulphuric acids, and heating to 125° for about an hour's time. The liquid is then poured into a rather large quantity of water; the hydrocinnamic acid which has not been converted into sulpho acid falls down as an oily liquid, which, after the fluid has become quite cold separates as a crystalline mass. The sulpho-hydrocinnamic acid is obtained pure, in free state, by means of the addition to the fluid, first, of some carbonate of baryta, and next baryta-water; and the hydro-

cinnamate of baryta is next carefully decomposed with just enough dilute sulphuric acid. Sulpho-hydrocinnamic acid thus obtained is a highly deliquescent, solid, crystalline substance. Its hygroscopicity is so great as to prevent its being obtained in sufficiently dry state for organic elementary analysis; but its composition, as deduced from the salts it forms with bases, is $C_9H_7O_5SO_3$. The author describes the following salts of sulpho-hydrocinnamic acid:—Acid sulpho-hydrocinnamate of potassium, $C_9H_7KSO_3$, obtained by carefully precipitating a solution of acid sulpho-hydrocinnamate of barium with neutral sulphate of potassa; the addition of alcohol to the aqueous fluid causes the precipitation of the compound potassa salt just named, which does not contain any water of crystallisation, and was, on analysis, found to contain 14.58 per cent of potassium. Neutral sulpho-hydrocinnamate of potassium, $2C_9H_7K_2SO_3 + H_2O$, obtained by neutralising a solution of the preceding salt.—This neutral salt crystallises in clinorhombic, prismatic-shaped crystals, from its concentrated solution in dilute alcohol; the salt contains 2.86 per cent of water, and 24.77 per cent of potassium. Neutral sulpho-hydrocinnamate of ammonium, $C_9H_7SO_3 \cdot 2NH_3 + H_2O$, obtained by dissolving the sulpho-hydrocinnamic acid in an excess of ammonia.—The salt crystallises spontaneously, but is obtained in more beautifully crystalline state by the addition of absolute alcohol to a warm and concentrated aqueous solution of the salt, which, in its anhydrous state, contains 12.88 per cent of ammonia. Acid sulpho-hydrocinnamate of barium—

crystallises most readily from a solution which contains a slight excess of the sulpho-hydrocinnamic acid.—The per cent composition of this salt is: Carbon, 33.39; hydrogen, 3.70; barium, 21.11; sulphur, 9.80; water, 8.12; oxygen, 23.72. Neutral sulpho-hydrocinnamate of baryta, $C_9H_7BaSO_3 + H_2O$, obtained by adding to a solution of the acid baryta salt a slight excess of hydrate of baryta; that excess is first removed by a current of carbonic acid, and, after filtration, the liquid deposits, by spontaneous evaporation, or by being heated on a water-bath, a white-coloured crust, of a non-crystalline mass. The salt contains 4.70 per cent of water and 37.57 per cent of barium. Acid sulpho-hydrocinnamate of cadmium, $C_{18}H_{14}CdSO_3O_{11} + 4H_2O$, contains 17.45 per cent of cadmium. Neutral sulpho-hydrocinnamate of silver, $C_9H_7AgSO_3$, a crystalline salt containing 48.43 per cent of silver. Acid sulpho-hydrocinnamate of copper, $C_{18}H_{14}CuSO_3O_{11} + 4H_2O$.—When a solution of the acid sulpho-hydrocinnamate of baryta is carefully precipitated with a solution of sulphate of copper, a green-coloured liquor is formed, which, on being concentrated, deposits a crystalline apple-green coloured salt, and a pale blue-coloured amorphous substance, which is the basic copper salt. The neutral salt contains 12.13 per cent of water, and in dry state, 12.06 per cent of copper. The formula of the basic copper salt is $C_{18}H_{14}Cu_2SO_3O_{12} + 3H_2O$.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 15, 1870.

This number contains the following original papers and memoirs:—

Contribution to the History of the Nitriles.—Dr. A. W. Hofmann.—After quoting a portion of a paper published by the author in the *Comptes Rendus* for September 6th, 1867, he proceeds to state—Isocyananil and cupronitrile appear to be the ends of a chain of isomeric bodies, between which there must exist a lengthy series of other bodies which have to be formed by the dehydration of butylamine acetate, propylamine propionate, ethylamine butyrate, and methylamine valerate. The paper contains, next, a series of lengthy formulae; and the author further proceeds to say that anhydrous phosphoric acid, which acts violently on ammoniacal salts, also causes considerable decomposition when allowed to act upon the salts of the primary monamines; it might, therefore, be preferable to act upon the corresponding monaminamides.

Beryllium Platinio-Chloride.—J. Thomsen.—Beryllium platiniochloride is very readily soluble in water, crystallises very easily, is deliquescent, but not altered when exposed to dry air. When rapidly crystallised, it forms an orange-coloured crystalline powder; when slowly crystallised, it forms short prismatic-like shaped crystals. The composition of this salt is $PtCl_4 + BeCl_2 + 9H_2O$. Heated to 120° , the salt loses five molecules of water, while the rest of that fluid is not even driven off at 200° ; the composition of the dry salt is, therefore, $PtCl_4 + BeCl_2 + 4H_2O$.

Alleged Derivation of the Law of Avogadro from the Mechanical Theory of Heat.—J. Thomsen.

Relation of Chemistry to Mineralogy.—Dr. C. Rammelsberg.—This paper, a lecture, is reserved for full translation.

Alloy of Lead with Platinum.—A. Bauer.—After referring to the observation of M. Deville, that an alloy of lead and platinum is readily decomposed in consequence of the conversion of the lead into white-lead, the author made an alloy, consisting of 3 parts of pure lead and 1 part of platinum. This alloy is so brittle that it can be readily pulverised; and the powder so obtained was moistened with water, and placed under a bell-jar exposed to the action of carbonic acid, oxygen, and vapours of acetic acid. The conversion of the lead into white-lead took place rapidly; and after it appeared that all the lead was converted into white-lead, the powder was treated with acetic acid, and the residue again exposed under the bell-jar to the action of the same substances. This process having been repeated several times, there remained at last a steel-greyish coloured crystalline powder, which only appeared to be finely-divided platinum. On being treated, however, with dilute nitric acid, the author found that the powder consisted of an alloy of lead and platinum, which contained, in 100 parts—Platinum, 45.82; lead, 54.18; corresponding to the formula $Pt + Pb$. This alloy has a sp. gr. of 15.77, is readily decomposed by mineral acids, but withstands boiling with acetic acid when rapidly

fused it is, after cooling, a bismuth-like, crystalline, very brittle metallic mass. The alloy, submitted in a muffle to the process of oxidising ignition, fuses, the lead is driven off, and platinum left.

This number contains a tabulated form, exhibiting the rules and prescriptions to be observed for disinfection, as drawn up by a committee of the Chemical Society of Berlin, and bearing upon the necessities occasioned by the war.

Bayerisches Industrie und Gewerbe Blatt, August, 1870.

This number opens with a lengthy communication, issued by the Bavarian Minister for Trade Manufactures and Home Affairs, concerning the—

Manufacture, Keeping, Sale, and Transport of Gunpowder, Gun-Cotton, Fireworks, and Detonating or Explosive Materials.—This communication, based upon Article 169 of the Bavarian Penal and Police Code, proves, in a very high degree, the eminent technical knowledge possessed by the parties by whose care this excellent regulation has been drawn up, so as to ensure perfect safety, yet not to hamper proper freedom of action, by all concerned.

The following original papers and memoirs relating to chemistry and collateral sciences are contained in this number:—

Fermentation.—Dr. A. Weinberg.—This very exhaustive memoir, a lecture given before the Chemical Society of Munich, contains a condensed review of all that has been done by scientific men to elucidate the phenomena of fermentation. The author ranges the different investigators of this subject into the following groups:—(1) Those who consider fermentation to be a purely chemical process, the result of the chemical action of the ferment or yeast on the sugar; MM. Trommsdorff and Meissner are the founders of this theory. (2) Those who consider fermentation to be a process of galvanic decomposition called forth by the dualism of the exciting body in a conducting fluid; this theory was founded by M. Kämtz, and among its adherents are MM. Schweigger, Colin, and Külle. (3) Those who consider it as a catalytic process, or as due to the action of porous bodies; this theory was founded by M. Berzelius. (4) Those who consider that fermentation is due to the action of certain nitrogenous matter, which is itself permanently in a state of decomposition, which is imparted to the sugar as soon as it (the sugar) comes into contact with the decomposing nitrogenous matter under favourable conditions—the consequence being the splitting up of the sugar into alcohol and carbonic acid; this view has been established by Dr. von Liebig, and is adhered to, among others, by MM. Frémy, Löwig, Gerhardt, &c. (5) Lastly, fermentation is viewed as being a kind of process of vegetation, the newly-formed yeast being considered as the newly-generated plant; this view is held by MM. Erxleben, Cagniard-Latour, Schwann, Dumas, Mulder, and others. The author relates the history of the views held on fermentation, as just alluded to, at some length, and winds up his lecture with a review on Dr. von Liebig's well-known essay recently published on this subject.

Drying of Wood.—R. Gottgetreu.—This paper is substantially the subject-matter of a lecture before the meeting of the Polytechnic Society of Munich in reply to the query, What means are applied at Munich for the proper drying of wood required for architectural, joiner's, and other purposes? The author enters, first, into a series of particulars relating to the very varying quantity of water (moisture and juices) contained in various kinds of wood at different periods of the year, from which it appears that, according to Dr. Hartig's experiments, woods (trees) generally contain, during the winter months, about an average of 50.7 per cent of moisture; in March and April, about 46.9 per cent; in May, June, and July, about 48 per cent; while up to the end of November the quantity of moisture increases but little. Air-dried wood (timber) contains from 20 to 25 per cent of water, and never less than 10 per cent. Wood which, by being artificially dried, has been deprived of all moisture, is thereby entirely altered as regards its cohesive strength—it becomes brittle, loses its elasticity and flexibility. In order to dry all kinds of timber by artificial means, so as to preserve the essential physical structure, and, thereby, the good properties of the wood, the drying should be effected slowly, and the temperature to which the timber is submitted should be moderate to begin with, and care should be taken not to eliminate all the water. The author enters into details, illustrated by engravings, on the best means of drying timber on the large scale, and states that small pieces of wood, such as are intended for joiners and furniture-makers, may be readily and efficiently dried by being placed in dry sand, and then heated to 100° . The sand acts in the manner of an absorber of the moisture, as well as a diffuser of the heat.

Some of the Reactions of Water-Glass.—Dr. F. A. Flückiger.—The author has instituted a series of experiments on the action of various salts soluble in water upon the so-called water-glass, solution of silicate of soda. As a general rule, the author found that the soluble salts of potassa, soda, lithia, and ammonia, more readily in water, possess the property of throwing down silica from a concentrated solution of silicate of soda. The experiments were made with a solution of silicate of soda of 1.392 sp. gr., which contained so slight an excess of soda that a single drop of alcohol, or a very weak acid, immediately precipitated silica from the solution. One part of this silicate solution diluted with 29 parts of water gives, with a solution of sal-ammoniac (1 of salt to 8 of water), upon being gently heated, a precipitate of silica. Caustic ammonia (sp. gr. 0.921) separates from the silicate solution, when cold, silica, but the precipitate is re-dissolved on heating. Propylamine also decomposes the silicate solution. The bromide and chloride of potassium in cold saturated solutions decompose the silicate solution on heat being applied, but not so in the cold. A drop of bromine, a single bubble of chlorine gas, a drop of creosote (Reichenbach's), a drop of carboic acid dissolved in glycerine, also dilute solutions of

albumen and gelatine, or glue, decompose the silicate solution, which is similarly affected by a solution of gum Arabic; while, on the other hand, other kinds of gum and mucilage, sugar, dextrine, glycerine, and urea do not decompose the silicate solution.

NOTES AND QUERIES.

Dextrine—Lactic Acid.—Is there any quick and ready process for determining the presence and quantity of dextrine in a vegetable solution? Can it be distinguished from glucose when present in the same liquid? What is the best mode of determining the presence of lactic acid?—CARBON.

Action of Light on Germination.—I remember reading in your journal, some years ago, a statement, made by some foreign chemist, I think, that placing blue glass in the windows of a malt-house will materially hasten the process of malt-making. I have since looked through the first eight volumes repeatedly, but have failed to hit upon the paragraph.—ALFRED ASHBY.

[We have looked through the *CHEMICAL NEWS*, also the general index to the *Jahresberichte über die Fortschritte der Chemie*, and, lastly, the *Table Générale des Comptes Rendus des Séances de l'Académie des Sciences* from 1835 to 1865. The only paper which relates to the subject is "De l'Influence Qu'exerce sur la Végétation des Plantes, et la Germination des Graines, les Rayons Solaires Transmis à Travers des Verres Colorés. M. Zantedeschi (*Comptes Rendus des Séances de l'Académie des Sciences*, vol. xvi., p. 71).—Ed. C. N.]

Condensation of Nitrous Vapours.—I observe, in the *CHEMICAL NEWS* of Nov. 4, R. Heilmann and P. Hart have introduced the use of lime for condensing the nitrous vapours evolved in the manufacture of H_2SO_4 . I beg to intimate that Mr. Barron, of Manchester, has used dry lime to condense nitrous vapours for the last ten years; and I believe I was the first to mix the solution of calcic nitrate with potassic chloride, to obtain potassic nitrate—

Practically, solution of $Ca_2(NO_3)_2$ cannot be distilled with H_2SO_4 in the ordinary nitric acid cylinders, owing to the acid acting upon the iron very rapidly. It must be in the solid state. Where magnesian sulphate forms part of the manufacture, I use lime made from dolomite limestone, which gives magnesian and calcic nitrates; and when distilled with H_2SO_4 , we get soluble $MgSO_4$ and insoluble $CaSO_4$. The mixture is digested with H_2O , a little CaH_2O_2 added, to throw down ferric oxide, allowed to settle, syphoned off, and boiled to crystallising point, &c. By the use of lime on the large scale I have condensed the vapours from the manufacture of nitrate of iron, used by dyers, &c., which, in reality, is a ferric sulphate, the whole amount of hydric nitrate being decomposed into nitrous vapours. Also the nitrous vapours evolved in the conversion of arsenic trioxide into arsenic pentoxide. I was told by a large aniline colour maker that he sent up his chimneys £100 worth, per month, of nitric acid; and his works are known by the name of "Red Smoke Works." Also the vapour evolved in making nitrobenzol from benzol. Iron turnings can be substituted for lime in the case of nitrate of iron.—H. H.

MEETINGS FOR THE WEEK.

- MONDAY, 28th.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action." (Educational Course.)
— Medical, 8.
— Royal Geographical, 8.30.
TUESDAY, 29th.—Institute of Civil Engineers, 8.
WEDNESDAY, 30th.—Society of Arts, 8.
— Royal, 4. Anniversary.
THURSDAY, Dec. 1st.—London Institution, 7.30. Prof. Morris, F.G.S., "On Gems and Precious Stones."
— Chemical, 8. W. H. Perkin, F.R.S., "On some Anthracen Derivatives."
FRIDAY, 2nd.—Geologists' Association, 8.

TO CORRESPONDENTS.

* Vol. XXI. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers. **READING CASES**, price 1s. 6d. each post free, may also be obtained at the Office.

ERRATA.—Page 242, column 2, line 20 from bottom, insert *nuclei*. Page 243, column 1, line 5 from top, instead of *analogous* read *anhydrous*. Professor C. A. Seely (New York).—Thank; our publisher will attend to your request.

Dr. E. M. Wetherill (Bethlehem, Pennsylvania). Your communication just to hand; it shall receive early attention.

W. C. Roberts. We are much obliged for the report.

R. K. Jaffock. Received with thank.

Rev H. Huxton. Your letter shall be inserted in our next.

Clem. Huxton, and Co. Received.

E. Ronalds. Forwarded.

A VICTIM OF THE WAR.

To the Editor of the Chemical News.

SIR,—I am quite sure I do not need to do more than ask the cosmopolitan Editor of the *CHEMICAL NEWS* to lay before the community of English manufacturing chemists the following extract from a letter received by a friend of mine in this city from Judge Neel, of Jersey, Channel Islands, and to whom, I may add, any communications on the subject of it might be addressed:—

"But the immediate object of my writing to you is to solicit your aid in finding a situation for a German gentleman whom this cruel Franco-Prussian war has thrown upon our shores. He was analytical chemist to the Western Railway of France, having Paris as his headquarters, with a salary of £400 a year. He was compelled to fly for his life, and was placed, by his employers, at Le Mons; after awhile, he was assailed there also, and has been obliged to leave France altogether. His former employers write him that the national feeling against the Germans is so great that it will not be prudent for him to return to France after the war, and that, therefore, he had better find a situation somewhere else. He wishes to remain in England. He has been placed, as it were, under my protection by a friend, and I feel great interest in him. He is a Lutheran protestant, single, but has a sister living with him, is twenty-nine years of age, and speaks English sufficiently well to make his way in England. He is a first-class theoretical and practical chemist and manipulator; an inventor; a translator of chemical works from German into French. He has given special attention to the utilisation of gas products; the manufacture of colours and dyes from coal-tar, of ammoniacal salts from the ammoniacal liquor, &c.; also to the manufacture of paraffin oils from petroleum and coal-shale, paraffin candles, &c. Would you kindly make enquiries, and let me know the result as soon as possible, as my friend's means are all but exhausted."

Should any one of your numberless chemical manufacturing readers have a vacancy which would enable him to obtain such an accession to his staff, he might, I think, serve both himself and his country in bringing a man of talent and technical skill to her shores.—I am, &c.,

FRANK SPENCE.

Manchester, Nov. 14th, 1870.

Just published, pp. 60, price 2s., cloth 2s. 6d. (postage 1d.),

Elementary Questions in Chemistry (for Schools). First series. Thirteen Papers on "Heat and Metals," by THOMAS WOOD, Ph.D., F.C.S., Lecturer on Chemistry at the Brighton and Lancing Colleges; author of "Chemical Notes," &c.

London: J. Helm, 10, Brownlow Street, Holborn, W.C.
Brighton: H. and C. Treacher, 1, North Street.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For instruction in Practical Chemistry and Evening Classes for the Study of Chemistry; Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870—1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Caesar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXII. No. 575.

ON THE ACTION OF NUCLEI ON SUPERSATURATED SOLUTIONS OF SODIC SULPHATE.

By CHARLES TOMLINSON, F.R.S.

I HAVE read with very great interest the paper by Mr. A. Liversidge "On Supersaturated Solutions of Sodid Sulphate," contained in the last two numbers of the *CHEMICAL NEWS*.

Being very much occupied just now with literary work, I am unable to reply to that paper in a manner worthy of its author or the subject, which he handles with fairness and skill—but I hope to be able to do so shortly. At present, I propose to make a few remarks on the first half of Mr. Liversidge's paper; the second half will require more time on my part than I can at present afford.

Mr. Liversidge does not see the bearing of the camphor experiment on the matter in hand, namely, the crystallisation of a supersaturated solution of sodid sulphate. He imagines that the film arising from a secretion from the finger "may act by arresting the evaporation both from the surface of the water and from the camphor, for the latter in its movements would pick up a coating of oily matter, through which evaporation would not readily take place."

This, I imagine, is not the modern view of the phenomena of the camphor movements as taught by Van der Mensbrugghe and confirmed by Plateau and others. The motions of the camphor fragments depend on the surface tension of the water; and the effect of the secretion from the finger is to degrade this tension from that of pure and chemically clean water to that of camphor julep, when, of course, motion of the fragments is no longer possible.

When a quantity of a newly distilled essential oil, amounting to about 10 or 20 drops, is placed on the surface of chemically clean water in a clean shallow glass vessel about 3½ inches in diameter, it assumes a lenticular form, and is separated from the water by surface tension. If now some fragments of camphor be scraped upon the surface of the lens or of the water, or both, they at once become very active, skating through the lens and cutting it up in all directions. A solution of the camphor in the oil surrounds each fragment, and an iridescent film spreading from it as it sails about gives it an elegant appearance, often so symmetrical as to make it appear like a small brilliant butterfly. But what I want to insist on is the different conditions of the oil lens and the camphorated oil film; the one is separated from the water by surface tension, the other is closely adhering to it, overcoming or greatly lowering surface tension.

Now, when a drop of a liquid is placed on the surface of another liquid, there happens (apart from chemical action), one of three things:—(1). It diffuses through the liquid, and in general does not act as a nucleus to a supersaturated solution of sodid sulphate. (2). It spreads out into a film. (3). It assumes a lenticular shape. It becomes a film or a lens according to the general proposition, that if on the surface of the liquid A, whose surface tension is a , we deposit a drop of the liquid B, whose surface tension b is less than a , the drop spreads into a film; but if b be greater than a , or only a little less, the drop will be lenticular. Hence, if B spread on A, A will not spread on B.

In my experiments on the nuclear action of films it was quite easy to distinguish between the action of the film as such and that of a speck of dust from the air or contained

in the film. When the film spreads so as to overcome the surface tension of the water, or rather when the surface tension of the water is lowered at the contact surface common to the oil drop and the water, the surface of the latter not so acted on exerts a tensile strain upon the drop outwards in all directions, and so spreads the drop into a film, at the same time drawing it into close adhesion with the surface. It is this close adhesion which constitutes the first step in the nuclear action of films, the second being that differential kind of action by which I define a nucleus. Now, supposing the film to be thus produced, large flat crystals with dihedral summits of the ρ -atom sodid sulphate are moulded, as it were, upon the lower surface of the film, parallel with it and limited by it, and as one set of crystals is formed and falls off, another set is produced, and yet another, until supersaturation ceases.

But when crystallisation sets in from a nuclear point or points, such as a speck or specks of dust, each point propagates its action downwards in minute crystalline lines at right angles to the surface or at angles of various magnitudes, and the crystals proceed to the bottom in close well packed lines, a phenomenon which is quite familiar; but I may be excused for the remark that the action of the film in forming large well-shaped crystals was, I believe, first described by me.

But now comes the question as to Mr. Liversidge's ingenious experiments, in which he succeeded about 120 times, or as many times as there were experiments, in placing thin films on his solutions without any separation of salt in any one case.

It will doubtless be granted that, in order for a film to act, it must be in contact with some part or other of the solution. If it be separated therefrom by surface tension it will not act. Mr. Liversidge, in order to get a film on the surface of his solution, makes an ethereal solution of the film-forming substance, and deposits a drop of that, trusting to the evaporation of the ether to spread out the film. Now any lowering of temperature increases surface tension, and my present impression is, that the evaporation of the ether so far increased the surface tension of the solution, that the film never once adhered to it, but was always separated from it by the superficial tension of the solution.

So, also, when Mr. Liversidge kept his clean finger in a solution lowered in temperature to 33° F., the surface tension of the solution was lowered thereby and the solution was separated from the finger by that tension. Had he been able to draw his finger strongly against the side of the flask, it is most likely crystallisation would have set in just as in my camphor experiment the fragments were brought to rest by a similar artifice. I have, on several occasions, kept my finger in highly supersaturated solutions of sodid acetate cooled down so as to be viscous, and protected from nuclei by a thin layer of oil, without any nuclear action, but on drawing the finger sharply against the side of the vessel so as to produce a *smear*, the whole became solid and very hot.

So, also, in the case of the glass rod and the greasy flask experiments—the solution rolled over them without wetting them. In other words, the solution or globules of the solution did not lose their surface tension to a sufficient extent to be brought into contact with the greasy surfaces.

Highgate, N.
November 28th, 1870.

PS. Since writing the above I have found time to perform two experiments.

Expt. 1.—A very strong solution of sodid sulphate was boiled in a large flask and then filtered into six small flasks, each of which was again boiled and set aside to cool, covered with a watch-glass.

Some oil of citronella, diluted with two or three times its volume of ether, was taken up in a straight dropping-tube furnished with an india-rubber shield, as described in my

mode of testing M. Jeannel's experiment (see *CHEMICAL NEWS*, vol. xxi., p. 52).

The watch-glass was gently removed from the flask No. 1, and the dropping-tube inserted; after some minutes a drop fell from the tube, the ether in spreading over the surface described its cohesion figure, and the solution crystallised immediately. In Nos. 2 to 5 the dropping-tube was lowered so as to deliver the drop very gently, or it was allowed to trickle down the side of the flask. In two cases the ether evaporated and left the oil on the surface in minute lenses; there was no crystallisation even on gently shaking the solution. In No. 4 a film was formed on the side of the flask; on inclining it so as to bring the solution into contact with it, crystallisation set in. In No. 6 a film was formed on the surface; but on gently shaking the flask the solution became solid.

Expt. 2—A very strong solution of sodic sulphate was filtered into eight flasks, which were re-boiled and covered as before and left undisturbed until the next day. The ethereal solution was made more dilute in order to avoid, if possible, the formation of lenses. The solutions Nos. 1, 2, 3, and 4 crystallised the moment the ether solution spread over the surface.

The ethereal solution was now made less dilute; that is, about 10 drops of the oil were diluted with about 20 drops of the weak solution. A drop or two of this was allowed to run down the side of No. 5, when the oil became lenticular. In No. 6 the oil in running down the side formed a film. On inclining the solution so as to make it meet the film, crystallisation at once set in. In No. 7 the dropping-tube remained some minutes in the flask, and the ether, instead of falling in a drop, evaporated, and the vapour condensed on the surface of the solution in the form of a well-defined circular film, from the lower surface of which a beautiful set of large crystals was produced. In the flask No. 8, the tube remained some minutes, and then a drop fell and spread, and the solution became solid.

I cannot help thinking that Mr. Liversidge's solutions are only just supersaturated. I have already hinted at this with reference to his former sets of experiments (see *CHEMICAL NEWS*, vol. xxii., p. 110). As far as my experience goes, results are not to be depended on unless the solutions are highly supersaturated, i.e., saturated, or nearly so, at the point of maximum solubility, so that a little anhydrous salt is thrown down at the boiling-point. I should also like to know the proportions of oil to ether used by Mr. Liversidge in making his films.

NOTE ON ITACOLUMITE (ARTICULITE).

By CHARLES M. WETHERILL, Ph.D., M.D.

I FEEL grateful to Professor A. M. Edwards, for having directed attention to itacolumite (*CHEMICAL NEWS*, vol. xxii., p. 111), although I cannot accept the correctness of his conclusions. I am not unfamiliar with the use of the microscope, which has held the place of honour in my laboratory for twenty years; nor were my inferences hasty, since I made careful examination of some forty specimens, being sections of different kinds of the mineral, cut in the plane of deposition, and at various angles thereto. I have been surprised that the wonderful structure of itacolumite, which seems to warrant the name I have proposed for it, has not attracted greater attention. This I can only account for by the natural incredulity which the announcement of such a structure would inspire, and in which I shared at first, believing that my eyes deceived me. It was only after long and patient examination that I became convinced of the nature of the joints, which are indeed very easily seen, and which I have shown to many visitors to our University. It would give me great pleasure to show them to Professor Edwards, whose difficulty appears to be in the interpretation of my words "ball-and-socket joints," in the idea that the motion "is much marked

in a direction at right angles at the lamination," and in the belief that the proof of the nature of the joints rests solely upon the microscope.

It may be said in respect to these—

(1). Each ball and socket does not admit of a great play, and is not smooth and perfect like that of the joint of a limb; it is, notwithstanding, perfect in principle of motion. The stone is built up of grains and congeries of grains loosely coherent, and forming irregular cavities in which are engaged projecting parts of other congeries or grains of sand, which are susceptible of a slight motion in the cavity—in some cases in one direction, and in others in several or in all directions. This freedom of motion is of the true quality of a ball-and-socket joint.

(2). The motion is *not* most "marked in a direction at right angles to the lamination." It is certainly so if a piece be taken of which the thickness is small in proportion to the other dimensions; but that is not the method by which the true motion is shown. A properly made section is susceptible of as much motion in the plane of lamination as at right angles to such a plane.

To prove this, I refer to the experiments (*American Journal of Science*, vol. xlv., July, 1867), upon a cylindrical rod of the mineral, 198 m.m. long and 13 m.m. in diameter, which was sawed from a thick block, and of which the axis was parallel to the planes of stratification. Supporting this rod upon two nails 185 m.m. apart, in order to determine the nature of the curve it assumed, the deflection was found to be essentially the same when the cylinder was rotated upon its axis on the supports. The difference was $\frac{1}{2}$ m.m. of its greatest deflection of $3\frac{1}{2}$ m.m., and had no relation to the stratification, being caused by a slight crack.

(3). The proof of the nature of the joints does not rest solely upon the microscope, although that alone is sufficient. The motions of the cylindrical rod afford an independent and equally convincing demonstration of the ball-and-socket character. There is no other kind of joint which could explain the motions which this rod is susceptible of, viz.:—"It can be compressed and elongated in the direction of its axis, the extent of motion being a little over $\frac{1}{2}$ m.m. When one end is fixed, the other end may describe a circle of 34 m.m. diameter, and may be made to touch every point in the area of the approximate spherical zone. The rod can also be twisted about its axis, the torsion being 10° ." I may add that, by shaking the rod near the ear, one may hear the clicking of the joints as the motion is arrested at the limit of their greatest play.

The nature of the curve (nearly a catenary) when the rod is supported by its ends, agrees with the joints which I have described, and confirms also the revelations of the microscope.

I have never seen anything so wonderful as this rod of itacolumite. When held by one end upward, it totters in all directions, so that no one, seeing it at a short distance, believes that it is a stone. A gentleman from California, to whom it was shown, suggested jocularly that it would do well to build houses with in his earthquake shaken state. Indeed, I have no doubt that a sufficiently high and thin well-built wall would be susceptible of a decided motion before cracking. The height of wall, so much greater than its thickness, would permit the play of the innumerable small joints, existing from the bottom to the top, to be perceived.

In order to see the joints, a thin section, supported at one end or at both ends, may be moved while under the microscope with a needle point; by changing the position of the section, a part may be reached at which the play of the joints may be perceived. They can also be seen by dissecting a flexible piece of the mineral, using either a fragment or a surface rubbed flat. The surface to be examined is inverted, tapped, and, as far as practicable, brushed free from loose grains. It is then examined under the microscope with a power of 40 to 60 diameters.

The attention of the observer is first attracted by the irregular pits or depressions formed by grains of sand.

By very delicate touches with a fine curved needle point, the surface may be investigated; loose grains of sand are seen and removed. Touching other grains and congeries of them delicately with the needle, proves that some have motion in a cavity formed of grains of sand cemented together. These are dissected out, and other movable groups are found. Some have less motion than others, and some are immovable. By patient investigation of the mineral in this way, the observer will rise satisfied that it is made up of joints of the character which I have described.

This mineral is worthy of greater attention than has been bestowed upon it. Why are some of its constituent grains cemented together in such a curious fashion, and not all of them? I hazarded an explanation which was the best I had, but which was unsatisfactory to me; doubtless, some other observer will be more fortunate. It would not be surprising if the elucidation of this point would throw some light upon the origin of the diamond. Has itacolumbite been found near the new diamond region of South Africa?

Bethlehem, Pennsylvania.

ON THE

COMPOSITION OF CRUDE SODA

(SO-CALLED SODA ASH OR BLACK ASH); AND ON THE LOSS OF SODIUM BY THE MANUFACTURE OF SODA ACCORDING TO LEBLANC'S PROCESS.

By M. A. SCHEURER-KESTNER.

As a result of investigations and researches made by me some few years ago on this subject, I found that crude soda contains, essentially, carbonate of sodium and sulphide and oxide of calcium in the proportion of from $1\frac{1}{2}$ to $1\frac{1}{4}$ molecules of calcium to 1 of sodium. The crude soda contains, moreover, all the foreign substances due to the impurities of the primary matters employed, as, for instance, silica, alumina, peroxide of iron, excess of carbonaceous matter, &c. Solutions of crude soda in water, treated with carbonic acid gas, after previous filtration to eliminate the matters insoluble in water, yields a white precipitate of silicate of alumina; this precipitate was found to be per centically composed of—Silica, 32.7; alumina, 44.0; water, 23.3;—formula, $\text{Si}_3\text{Al}_2\text{O}_{12} + 6\text{H}_2\text{O}$. By re-crystallising several times the soda contained in the solution just alluded to, the mother-liquors of these operations will contain the bulk of the impurities. Beside oxygenated sulphur compounds, I have found, in these liquors, seleniate and sulphocyanide of sodium. The selenium is derived from the sulphuric acid which has served for the preparation of the sulphate of soda, the acid alluded to having been made from the Chessy (France) pyrites, which contain a small proportion of selenium. The sulphocyanide of sodium is due either to the action of the air upon the soda while in pasty fused state, or is derived from the nitrogen of the coals which are used in the reduction process. The presence of this sulphocyanide is the cause of the ammoniacal smell given off by the ball soda while exposed to moist air for the purpose of cooling. In order to prove the presence of the compound just alluded to in ball soda, it is only necessary to exhaust it with alcohol; the ensuing solution is somewhat coloured, the colouration (either red or yellow) being due to traces of croconate and rhodionate of sodium. I found, by treating 100 grms. of crude soda with alcohol, and evaporation of the liquid, 73 milligrams. of sulphocyanide of sodium. The seleniate of soda is found by precipitating the mother-liquors with a soluble salt of lead until the ensuing precipitate ceases to be coloured; by decomposing this precipitate by means of sulphuretted hydrogen, a mass is obtained which, when ignited, gives off the characteristic vapours of selenium. All the substances just alluded to occur in the normal crude soda; but, if

that substance has been over-heated (too strongly ignited), it also contains sulphide of sodium, NaS , derived from the reaction of the carbonate upon the sulphide of calcium. $2\text{CaS} + \text{Na}_2\text{CO}_3 = 2\text{NaS} + \text{CaO} + \text{CO}_2$.

Loss of Sodium during the Preparation of the Soda.—It is a well-known fact that, when working on the large scale, Leblanc's process does not yield, in practice, anything like what, according to calculation and theory, should be obtained. There is a loss of soda attributed by many chemists (including Dr. Unger, who found the loss from volatilisation of sodium alone to amount to one-fifth in one operation; while Dr. Stromeyer also ascertained the volatilisation of this metal, while experimenting on the large scale to carry out M. E. Kopp's process of soda making, by treating sulphate of soda with coal and oxide of iron) to volatilisation of metallic sodium occurring during the fusion of crude soda in the calcining furnace, because the soda retained as a soluble salt in the residue (waste) is not sufficient to account for the total loss.

The residues, or soda-wastes, are always found to retain a certain quantity of soda as soluble salts; but they contain a far greater quantity of soda in a state insoluble in water. The loss of soda incurred during the process of manufacture is therefore due to several causes, and among these—(1) to volatilisation of sodium in the calcining furnace; (2) soluble salts of soda retained in the waste in consequence of imperfect lixiviation; (3) soda retained as insoluble compounds in the waste; and (4) loss due to the manipulations of the liquors and salts during the process of manufacture. In order to determine the quantity of sodium volatilised during the calcination, it is required to operate upon materials of well-known composition, and estimate the sodium very correctly in all the products obtained. I am indebted to the kindness of M. Usiglio, who has made a series of such experiments, for his communications on this subject, especially the full account of his method of experimenting, which is so correct and good as not to leave anything to be desired.

Average samples of the sulphate of soda, chalk, and coal intended to be furnaced have been taken, and the quantities to be furnaced, as well as the ball soda, have been weighed as exactly as possible, and samples of all have been analysed with great accuracy, so that by these means, we could come to the knowledge of the quantity of sodium volatilised. My experiments, as well as those of M. Usiglio, have proved that, during the conversion of sulphate of sodium into crude soda (ball soda), no volatilisation takes place at all. The whole of the sodium originally present in the sulphate of soda is found in the crude product; but, if the furnace-temperature is too high, a small quantity of chloride of sodium is volatilised. Upon 1216 kilos. of sodium, as present in 3965 kilos. of sulphate of soda, I have found, in 6558 kilos. of crude soda, 1216 kilos. of sodium again. M. Usiglio has estimated quantitatively, in the raw materials, as well as in the crude product, the relations existing between the calcium, sulphur, and the sodium, and found—

	In the raw materials.	In the crude soda.
Sodium	31.68	31.49
Calcium	45.66	45.62
Sulphur	22.66	22.89
	100.00	100.00

If, therefore, any volatilisation takes place at all, it is clear that one should have to admit that the three elements—sodium, calcium, and sulphur become volatilised exactly in the same proportion. Since it is thus proved that, under ordinary conditions, no reduction nor volatilisation of soda-salts and sodium takes place during the furnacing process, we have to look, therefore, in another direction for the causes of the loss of sodium daily experienced during its manufacture. The chief seat of this loss is proved to be the so-called soda-waste, which generally, it is true, retains, after lixiviation, only about 1-rootth of soluble soda-salts; but the quantity of salts of

that base contained therein in the state of combination insoluble in water varies considerably. For instance, M. Unger found that the total quantity of soluble and insoluble sodium amounted, in the wastes of the Rinckuhl Alkali Works, to 1.06 per cent; M. Kopp* found the waste of the works near Dieuze to contain 4.36 per cent; Mr. Brown† found the waste of the works at Cassel to contain 1.01 per cent; and Dr. Muspratt‡ states that the average at the Newcastle-on-Tyne alkali works amounts to from 1 to 2 per cent of sodium retained in the waste. I have had ground up 4000 kilos. (4 tons) of soda waste, and, after having thoroughly mixed this mass, have taken a fair average sample, which, after drying, has been analysed and found to contain—Insoluble sodium, 1.67; soluble, 0.17;—total, 1.84 per cent sodium. Another experiment, made with an average sample again taken from the quantity just alluded to, but not the same waste, has yielded—Insoluble sodium, 0.99; soluble, 0.43;—total, 1.42 per cent sodium. Since crude soda (black ash) leaves about 60 per cent of waste, and contains about 18.65 per cent of sodium, there results a loss of about 5 per cent of sodium in the state of insoluble compounds of that metal as retained in the waste.

The true nature and precise composition of this compound are unknown; the bluish hue of the waste favours the correctness of the opinion expressed by some makers that some ultramarine is formed. M. Kopp calculates this substance as sulphuret of sodium; and Mr. Brown notes it down in one of his analyses as sulphuret, and in another, again, as carbonate. The differences observed between the laboratory experiments made on crude soda and the results obtained by the lixiviation on the large scale, appear to indicate that a portion of the soda is rendered insoluble in water by its prolonged contact with water and the sulphides of the waste. However this may be, my researches prove—(1) that during the calcination process (furnacing) no soda-salts are reduced to metallic sodium; and (2) that the greater part of the loss of sodium is due to the formation of insoluble sodium compounds which are retained in the waste, a loss which certainly is never less than 5 per cent, and often very much larger.

ON THE FUSIBILITY OF PLATINUM IN THE BLOWPIPE FLAME.

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

THE metal platinum has hitherto been supposed to be infusible, except at a temperature that is so high, as to be incapable of being produced by the common blowpipe; at least I have carefully searched for any statements to the contrary without success.

When I was lately engaged in studying the effects of the hot-blast blowpipe flame, the results of which investigation have already been communicated to the Wellington Philosophical Society, I found it necessary to test, with accuracy, the degree of fusibility of platinum; and discovered that if the loss of heat from the flame, by conduction, was guarded against, platinum can be fused with an ordinary blowpipe blast through a candle flame. The method adopted was to substitute, for the metallic nozzle generally employed, a tube of clay or glass, either of which is a feeble conductor of heat, as compared with metals.

By this means fine platinum points were fused in an unmistakable manner to beads. The blast was that ordinarily used in the laboratory by the use of the hydrostatic blowpipe, the flame being that of a stearine candle.

As it might be urged that, perhaps, the platina I treated might contain an admixture of more fusible metal, and that its melting-point might thus be reduced, I prepared

some of the platina for special trial, which was absolutely free from such fusible metals.

As the fusing point of platinum has been ascertained to be 4593° F., we must, from the above experiment, conclude, that if proper precautions are taken to prevent loss of heat by conduction, this high temperature can be produced by the ordinary blowpipe operating upon flames of this description.

ON FERMENTATION.*

By Professor A. W. WILLIAMSON, F.R.S.

(Continued from p. 248).

Then there are some other processes of considerable importance, from their occurrence in the animal economy—processes which, I believe, must be classed between those experiments which I showed you a little while ago and the process of fermentation—I mean processes which occur in the operation of digestion. I have here a gelatinous solid, which contains a substance called pepsin, which was made by dissolving the inner lining of a pig's stomach in diluted hydrochloric acid at about blood heat. The inner lining of the stomach of that and similar animals is dissolved gradually, and that solution possesses the property of dissolving muscular fibre, white of egg, and other similar substances; it is, in fact, artificial gastric juice, and it would, for instance, dissolve that lump of gluten which I showed you just now—which looked something like india-rubber—and when this pepsin dissolves albumen by digestion, for the process is doubtless of the same kind as that which occurs in the animal economy, it does so by breaking it up into bodies which are, no doubt, simpler than itself, bodies which we do not know accurately and fully. They are called peptones, for it is common enough to give names to bodies, even before one knows them well. I do not know whether it is a good plan, but it is customary. These bodies are a good deal similar to those which are present in malt, and in such like mixtures which have undergone vital changes.

Then I will give you one or two other cases of similar processes. Here is a singularly beautiful acid, called hippuric acid, which decomposes with very great readiness if left in the liquids in which it is originally found. When that organic mixture is exposed to the air it undergoes a process of putrefaction. The general appearances which take place in the liquid while the substance is decomposing would certainly be described by anybody as a putrefactive process, and there is formed by its decomposition some of this other beautiful acid, called benzoic acid, because it was originally obtained from the fragrant gum benzoin. At the same time there are other products given off which decompose. Now, we can by mineral substances, effect the same decomposition of that hippuric acid. A German chemist, to whom we owe many researches in these matters, showed, some years ago that, if you boiled hippuric acid with dilute sulphuric acid, it takes up water, and breaks up into benzoic acid, and this crystalline substance, called glycol, or sugar of glue. It got that name from the circumstance that it was obtained originally from glue by a decomposing action, and it has a sweet taste. It has no analogy to sugar, in its nature, but it has that superficial resemblance that it is rather sweet.

This hippuric acid affords another case of a body which is broken up either by putrefaction, or by the action of dilute sulphuric acid. It affords a strong argument, and other cases I have adduced afford, like it, an argument that the action of these organic substances resembles the action of dilute sulphuric acid. If we get the same change in several cases by the action of an organic body as by the action of a mineral body, the fact certainly goes some way towards showing that the two substances must be, in their mode of action, generally alike. There is another case, that of urea, which in contact with water

* The Cantor Lectures. Delivered before the Society of Arts.

forms a carbonate. That may be done by either class of reagent.

There are, however, some chemical processes even simpler than these, and for that reason they are better known to us, which really may be studied with advantage side by side with those I have mentioned, and they will, I think, afford us, on further consideration, a key to the explanation of these processes. I will only mention two. One is a process which is well-known in its general features, and it is a process of breaking up truly analogous to those I have mentioned, but a perfectly simple breaking up of alcohol into two substances, both of them well-known now, one being water, and the other ether. It is a process which consists in dividing the elements of alcohol in such a way as to get nothing formed but these two products, though side by side with this change there are some secondary changes which do not belong to the process. This change is effected solely by the action of oil of vitriol or sulphuric acid. It has been long known, and it was a subject of wonder for some time that, if sulphuric acid is mixed with alcohol and heated, you can distil off some alcohol from the mixture in the form of these two products; then you may add some more alcohol, and if you distil that off, it is also broken up into ether and water; then you may add some more again, and you may go on adding alcohol to that original quantity of sulphuric acid, and it will decompose each successive portion into these two products. There is no limit known to the extent to which sulphuric acid will effect that change. You perceive, therefore, that this, in its general features, is a process analogous to those which we were considering at first.

I may illustrate that by an experiment. First, I will show you how we discover the presence of sulphuric acid. The common test is to add some salt of baryta—this which I have here is a chloride—to the sulphate, when we get at once a precipitate sulphate of baryta. The sulphuric acid, in making the ether, passes over into a compound that does not possess this property. I have some of it here. It is a clear liquid, and on mixing it with the same reagent I used just now you see that it will not form the precipitate. I put some of the same baric chloride into it, but, as you see, the liquid remains clear. But I can bring back my sulphuric acid to its original state. Mr. Taylor, my assistant, was heating some of it just now, and it has been standing so long that it has returned to its original state already. It has returned from the state in which it does not precipitate baryta to the state in which it does. There is in the process a successive departure of the sulphuric acid from its ordinary state, and a return to that original state; it is a kind of circle or cycle. The substance passes over into a compound which does not precipitate baryta, and then it returns again to its original form, and that is the key to the anomaly. When the sulphuric acid has effected the decomposition of one portion of alcohol into ether and water, it comes back again to sulphuric acid, becomes exactly what it was in the beginning, and is able to recommence precisely the same combination. I will give you another example of it. I have here a substance used in one of the commonest manufactures, that of oil of vitriol, in which the same operation occurs. I have there a substance at work called nitric oxide. It is converting a quantity of sulphurous into sulphuric acid. In principle it would so convert an infinite quantity, but in practice it is limited by convenience. It acts by carrying oxygen from the air to one portion of sulphurous acid and then to another, and thus it goes on, and effects successive oxidations of a great number of particles of sulphurous acid, forming sulphuric acid from them, and it does that in virtue of a process perfectly analogous to that which I just now mentioned. The gas, after one operation, returns to the same state in which it was in the beginning of the first operation; it is a cyclical process. I have here some of the nitric oxide combined with oxygen, and when in that state it has the red colour which you see in the flask. If we blow a little sulphurous acid into it, the red colour will disappear as

the nitrous acid gives up the oxygen, the nitric oxide itself being a colourless compound, but in combination with oxygen it is red. As the sulphurous acid passes into it, the nitric oxide parts with the oxygen and becomes colourless, but on again blowing in a little oxygen it returns to its former red colour. This shows you that there are processes, of simple, normal, chemical action, somewhat analogous to those fermentive properties which I formerly described. Each one of these processes takes place in perfectly definite proportions, the peculiarity being that one material which takes part in them returns at the end of one operation to the same state in which it was at the beginning of the operation, so that the processes are cyclical, and this reagent is able, by acting successively on a large quantity of particles, to repeat its action very frequently upon them, and beyond what would appear to be its definite combining proportion. You see this red compound of nitric oxide and oxygen has lost a great deal of its red colour. I will not wait until it is completely bleached, but will blow in a little oxygen, when we shall get a return to the original deep red colour. This is the ordinary process by which sulphuric acid is made on a large scale in lead chambers. The sulphurous acid is allowed to remain a considerable time in the chamber, and is passed on from one to another, as it is acted on by the nitric oxide, which passes through the successive stages of its action by a process which I should be glad to name cyclical, as I shall have occasion again to revert to a similar process of the same name. At our next meeting I shall have to analyse some of the best known, and also some less familiar instances, of cyclical action, that we may arrive at a conception of their nature.

(To be continued).

ON THE INTRODUCTION OF THE PRINCIPLE OF REPETITION INTO CHEMICAL ANALYSIS.

By BRYANT GODWIN.

THE method of repetition, so frequently and so advantageously employed in physical investigations, has not, so far as I am aware, been applied to chemical analysis. It seems, at least, desirable that it should be so applied, and I will here give a particular instance in which it may be employed with advantage. In the determination of iron by means of potassic hypermanganate, all the iron is, at the end of the operation, in the form of sesquioxide, while there is also a very small excess of unreduced hypermanganate. When the solution is boiled for a short time with pure zinc-dust, and then filtered through a ribbed filter, which is quickly washed with water previously boiled to expel air, the iron is wholly in the form of ferrous oxide, and the process of titration may be repeated a second time. After a new reduction, the iron may again be determined, and this process may be repeated until the volume of liquid becomes too large to be easily handled. The following analyses were made to test this process:—

0.4725 gr. ammonio-ferrous sulphate required, in five successive titrations, 49.0, 47.2, 48.7, 48.0, and 48.5 c.c. of potassic hypermanganate, 1 c.c. corresponding to 0.0014 gr. iron. The mean of these five determinations gives 14.31 per cent iron in the salt.

0.4888 gr. required, in seven successive titrations, 49.5, 48.75, 50.5, 49.8, 49.7, 49.8, and 49.5 c.c. of hypermanganate, the mean of which gives 14.23 per cent iron.

The formula requires 14.27 per cent.

These analyses, which, with more practice and experience on my part, would doubtless have corresponded much more closely, will at least serve to show that the principle of repeated observations of the same quantity to be measured may sometimes be introduced into chemical analysis.—*American Journal of Science.*

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL
SOCIETY.*Ordinary Meeting, November 15th, 1870.*

E. W. BINNEY, F.R.S., F.G.S., President, in the Chair.

JOHN DURHAM BIRD, M.D.; Mr. John A. Bennion; Henry Deacon, F.C.S.; Mr Joseph Carter Bell, and Thomas Steadman Aldis, M.A. were elected ordinary members of the Society.

Mr. W. B. JOHNSON, C.E., brought before the notice of the meeting the extraordinary advance that had been made within the last twenty years in the capabilities of machines for cutting and paring heavy articles of machinery, and said this was particularly noticeable in the treatment of heavy forgings. At no very remote date it was the universal practice to pare down heavy forgings to something near the finished dimensions in the smithy by hand labour only; this mode of procedure was not only expensive, but rude and imperfect in its results. The introduction of tools to supersede the use of the hand chisel and file in the workshop has been developed to a remarkable degree. Machines are now made of such enormous strength, and the cutting tools so carefully devised, that the old system of paring down in the smithy has been set aside; this competition between the tools of the workshop, and the handwork of the smithy has resulted in establishing the system of tool paring in preference to smith-work to an almost universal extent. Twenty years ago there might be seen in engineering establishments a large smiths' fire, in which was placed a part of some heavy forging, and when the part under operation was heated to a blood-red heat, the superfluous parts were cut off by means of a set, upon which the successive blows of four and sometimes six strikers were delivered with surprising precision and regularity, and by these repeated heatings and dressings the forging would be eventually brought down to its finished dimensions, except by so much as was necessary for the final finishing or getting up. These operations in the smithy, as before observed, have now ceased; the forgings are taken at once and placed in a machine, which, by heavy and continuous cutting, soon pares down the forgings, and then finishes them without changing them to another machine or process. Tool paring is not only economical of labour, but the result as to accuracy is more satisfactory. Mr. Johnson then showed to the meeting some specimens of steel and iron parings sent to him by Messrs. Smith and Coventry, machinists, Salford, and further remarked that these parings demonstrated very clearly the capabilities of the machines and cutting tools of the present day. One specimen from a Bessemer steel shaft, the result of taking a cut of $\frac{1}{16}$ ths of an inch deep by $\frac{1}{16}$ ths of an inch traverse, was particularly interesting on account of the form and size in which they, the parings, left the cutting tools. The cutting tools used in obtaining the specimens exhibited to the meeting were of a peculiar construction, and possessed some marked advantages over those in ordinary use.

On the Temperature Equilibrium of an Enclosure containing a Body in Visible Motion, by BALFOUR STEWART, LL.D., F.R.S.

It has been established that in an enclosure containing bodies which are all at the same temperature, and at rest, the same amount of heat enters any surface forming part of the walls of the enclosure as leaves it in the same time, so that the body, of which this is the surface, neither gains nor loses heat. It is also known that if we take not the outer surface of such a body, but any plane passing through its substance, say, for instance, one parallel to its outer surface, then as much heat passes across this plane going into the body as passes across it going out of

the body in the opposite direction; and further, this equilibrium of heat is known to hold separately for every one of the individual rays of which the whole heterogeneous radiation is composed.

The effect of the motion of the body in altering the wave-length of the radiated light is also well known. In consequence of this, if a cosmical mass, such as a star or nebula should be formed of incandescent hydrogen, and be at the same time rapidly approaching the earth, the light which strikes the earth will not be the double line D, but a line more refrangible than it, and therefore this light will be able to pass through a mass of ignited sodium vapour at the earth's surface without suffering absorption, while, however, the light emanating from the sodium vapour will still be the double line D.

In such a case, even if the star and the terrestrial sodium vapour should both be of the same temperature, yet the light radiated by the latter will not be the same in quality as that absorbed. This instance would appear to show that the equilibrium which holds in an enclosure of uniform temperature when all the substances are at rest does not hold when some of these are in visible motion, and that if in that enclosure there be a body moving towards or from the surface of the enclosure, the heat which enters the surface from the moving body will not be the same as that which the surface gives out.

Suppose, for instance, that the walls of the enclosure are made of glass, and the temperature of the whole enclosure, including that of the moving body, is 0° C., then, were the whole at rest, the heat which strikes the glass surface will all be absorbed at a very short distance below the surface, and in like manner the heat radiated by the glass will all emanate from a short distance below the surface. But let us now suppose, to take an extreme case, that the moving body is approaching one of the glass surfaces so rapidly that the heat which it emits has been so much increased in refrangibility as to enter the boundary of the visible spectrum.

Then while the heat radiated by the glass will still continue to proceed from a very short distance beneath the surface, the heat absorbed by the glass from the moving body will be able to penetrate to a very considerable depth beneath the surface of the glass.

The outer layer of glass will thus lose, while the inner layer will gain, heat.

Now, it is possible to conceive an enclosure with a fixed diaphragm, and containing a revolving body, so arranged that the heat which leaves it in the direction of a certain part of the enclosing surface, shall always be given out by that part of the revolving body which is moving towards the surface; while, on the other hand, the heat given out by the revolving body to another surface shall be given out when the revolving body is moving from that surface.

There will thus be a want of temperature equilibrium among the various layers, those near the surface being somewhat different in temperature from those beneath. But when we have a temperature difference of this kind, have we not acquired the power of converting heat into work? It would thus appear, at first sight, that the mere presence of a moving body has given us the power of obtaining work from an enclosure, all of whose particles were originally at the same temperature. This appears, however, to be opposed to the theory of the dissipation of energy, and in consequence we are induced to think there must be some error in the assumption.

Now, does not the unwarranted part of the hypothesis consist in our supposing that the revolving system can continue to revolve without losing part of its visible motion?

When two moving bodies approach or recede from each other, is it not possible that each loses a small part of its visible energy while at the same time there is a surface disturbance produced in both?

It might be said that believing in a medium pervading all space we were prepared for a stoppage of motion of this nature, and that there is, therefore, nothing gained

by the supposition which has been made; but it might be replied that, by looking at the problem in the above light, we appear to connect this stoppage of motion with other facts, besides being made aware of a source of surface disturbance when cosmical bodies approach or recede from each other.

Postscript, added November 19th.—If we imagine a stoppage of the motion of cosmical bodies of the nature above described, then if the two approaching bodies be exactly equal and similar, either extremity of the medium between them will be similarly affected by the motion derived from the approaching bodies; but if these bodies are unequal, the two extremities of the medium will be dissimilarly affected.

MICROSCOPICAL AND NATURAL HISTORY SECTION.

November 7th, 1870.

JOSEPH BAKENDELL, F.R.A.S., President of the Section, in the Chair.

MR. BAKENDELL reported that, in accordance with a wish expressed by the Council of this Section, the Parent Society had agreed to an alteration of the rules respecting the admission of Associates to the Section; in future the subscription for Associates, with the present privileges, will be 10s. per annum, and to those paying a subscription of 20s. per annum, the right of taking books out of the library will be accorded.

MR. SPENCER BICKHAM, jun., called attention to the very serious inconvenience that was experienced by all having occasion to distribute Natural History specimens, owing to the recent prohibition of the authorities to allow such parcels to be transmitted by "sample post," and it was agreed that a memorial be forwarded to the Postmaster General.

LONDON INSTITUTION.

ON Thursday evening, November 24th, Professor MORRIS, F.G.S., delivered a lecture "*On the Precious Metals and their Distribution.*" The chair was occupied by Mr. H. W. FIELD, F.C.S., Resident Assayer at the Royal Mint, and many other gentlemen interested in the working and manufacture of the precious metals were among the audience. In the first part of his lecture, Professor Morris brought forward a vast array of facts relating to the use of gold and silver by the ancients, particularly the Egyptians, who seemed to have obtained their supplies of the former metal from Nubia. The lecturer dwelt at length on mode of occurrence of the precious metals, their geographical range, geological position, and economic uses, illustrating his remarks with maps, models of nuggets, and numerous beautiful specimens of native gold. In discussing the geology of gold, he said that this metal was found distributed through rocks, quartz veins, or alluvial deposits. The Silurian rocks, and the granites associated with them, furnished the greater quantity, but the cretaceous-oolitic rocks of Peru, Bolivia, and California when, traversed by dioritic igneous rocks, were also auriferous, showing, according to Mr. David Forbes, that there were two well-marked epochs of gold-intrusion. From both formations, but specially from the Silurian, the gold found in alluvial deposits is derived, the auriferous rocks having undergone erosion to an enormous extent at a comparatively late geological period, namely, the Newer Pliocene. The remains of extinct mammalia, discovered in the deposits of the Urals, and also in those of Australia, had satisfactorily fixed their geological age. In noticing the more important points connected with the gold coinage, Professor Morris referred to the remarkable brittleness of gold alloys containing minute quantities of palladium.

On Monday afternoon, November 28th, Dr. ODLING delivered the fifth lecture of his educational course, "*On*

Chemical Action," to a crowded audience, comprising a large number of boys and girls from the schools of London and its environs. In this lecture the chemistry of burning or destruction was entered on, and almost every fact brought forward was the subject of a striking experiment.

CORRESPONDENCE.

ON THE MAGNETIC POWER EVOLVED BY A GALVANIC BATTERY.

To the Editor of the Chemical News.

SIR,—In your journal of the 28th ult. (CHEMICAL NEWS, vol. xxii., p. 205), there was an abstract of a paper by the Rev. H. Highton, "On the Maximum of Magnetic Power Evolved by a Galvanic Battery." In that paper Mr. Highton says—"Can we, then, get infinite power out of a finite source of force? Yes. But on this condition, that what we gain in power we lose in time; for the current would take twice as long to traverse the second circuit, and therefore it takes double the time to produce double the magnetic power. But the electric current is so rapid that this difference of time is inappreciable within any practical limits." It appears to me that this last sentence entirely nullifies the previous remark, that "what we gain in power we lose in time"; in other words, I understand Mr. Highton to assert that we can obtain infinite power out of a finite source of force. Does Mr. Highton attach different meanings to the terms "power" and "force"? These terms are usually considered to be synonymous. If they are, the above statement is a logical contradiction in itself; if, in Mr. Highton's opinion, they are not synonymous terms, might it not be advisable for him to define what are his conceptions of the meanings of the terms "power" and "force"?

In another place, speaking of doing work, Mr. Highton says—"But this work is being done every time that the circuit, after being broken, is closed; and the circuit may be broken and closed so many times a second, that the number is practically illimitable, and hence the amount of work that can be done by a given battery is illimitable. The only question is a question of first cost of machinery."

Now I presume that Mr. Highton means, by a "given battery," one capable of distributing a definite quantity of force. Referring to the above paragraph, it would appear that the source of force (the battery) was governed solely by the operation of breaking and closing the circuit. Is the magnet itself a progenitor of force? Mr. Highton does not say.

Furthermore, is Mr. Highton aware of the fact that, in practice, it is found that a "given battery" will not supply the requisite amount of force for an unlimited quantity of magnetic machinery? Possibly I have misunderstood Mr. Highton's statements; but, as the subject is of great interest, I should feel obliged if you would insert this letter in your valuable journal.—I am, &c.,

ROBERT SPICE.

40, Cirencester Place, W.,
Nov. 17th, 1870.

ON THE MAXIMUM OF MAGNETIC POWER EVOLVED BY A GALVANIC BATTERY.*

To the Editor of the Chemical News.

SIR,—I gladly avail myself of the opportunity afforded me by Mr. Spice's letter, which you have kindly communicated to me, to enter more fully and deeply into the question raised by me in my paper read before the British Association.

Let me first, then, define what I mean by "force" or "power," which, as Mr. Spice justly observes, are synonymous. I will define, then, in this connection, the

* To save time, Mr. Spice's letter was forwarded in proof to Mr. Highton, and we are thus enabled to lay before our readers this reply.

amount of magnetic force or power to be "the number of units of weight which the magnet will raise through a unit of height." In the case of a magnet, the unit of height taken should be small, because the power varies considerably (generally inversely as the square) at different distances. I might define magnetic force to be the amount of weight which a magnet will sustain, which is in proportion to the weight raised through a unit of height, but it might be objected that this is only a static, not a dynamic, force. It might be defined in many other ways, but I think this will answer the purpose and be as simple as any. It might be measured by the method of torsion, or the number of oscillations caused in a second in a magnetic needle. While I am giving definitions, let me say that by "a given battery" I do not mean "one capable of distributing a definite quantity of force," for that involves the very question at issue; but I mean a battery of a given number of cells, with elements of a given size and of a given material, at a given distance from each other in a given electrolyte; and by the maximum of magnetic power evolved by it, I mean the maximum power evolved by a given consumption of zinc or other positive element. It has always been assumed, as a kind of axiom, that a given battery, by a given consumption of zinc (or a given amount of chemical change), can only produce a certain maximum of force. Now the question I wished to raise was whether this was true; whether facts, and the ordinary accepted laws based on facts, did not show that a given amount of chemical change could, by skill, be made to produce any amount of force whatever. I do not care to defend the suitability of the terms or manner in which I expressed myself in the abstract of my paper read at the last meeting of the British Association; but what I do wish is to raise this grand question.

I am quite aware that, at present, the majority of the scientific world would at once decide in the negative *a priori*—and perhaps refuse even to discuss it. But it is a question, not of preconceived theory, but of fact. When Galileo dropped weights of one pound and ten pounds from the tower of Pisa, and the sound of their collision with the ground rung on the ear simultaneously, the scientific men of the day refused to believe their senses, because Aristotle had shown that a ten-pound weight must fall ten times as fast as a one-pound weight. But facts have since proved too strong for theory. I freely confess that I was indistinct and obscure in my mode of expressing myself in the paper above mentioned, and therefore let me now state distinctly that what I wish to assert, as at present advised, is that a given amount of chemical change can be made (I do not say economically or conveniently, but *can* be made) to produce an unlimited amount of force. I wished in the reasoning and experiment given in that paper to show that whatever amount of force a battery was producing, that amount might be doubled or, in fact, increased indefinitely.

To simplify the matter, let me take the simplest possible case. Take a battery with an exterior circuit consisting of one electro-magnet, which shall be capable of sustaining n pounds when the circuit is closed. Then I assert that if for the one electro-magnet n electro-magnets be substituted, and the current passed in succession through them, each electro-magnet will sustain one pound, and also that if in the first case the battery were consuming n grains (or other units) of zinc per second, it will now only consume one grain, so that the consumption of one grain of zinc will now produce as much force as n grains did before. I may say, indeed, that, as a matter of fact, each magnet in the second case will sustain rather more than one pound, for, on account of reasons which it is not worth while here to enter into, the magnetic force will decrease rather less than in proportion to the intensity.*

* I have since found this to be strictly true only when the experiment was tried under certain conditions. What is strictly true is, that the power of the wire to act on a magnet follows this rule. The actual weight sustained by a magnet depends on numerous subsidiary conditions.

But, to probe the matter to the bottom, we must divide the time during which the battery acts into three periods, and describe what takes place during each. (1) The time which it takes the electric force to traverse the circuit after it is closed. This in ordinary cases is infinitesimal; but where the circuit is very long, and where there is much inductive as well as conductive resistance, as in the Atlantic Telegraph, the time becomes very appreciable. But I would remark that the expenditure of zinc during this first period is occupied in producing a state of tension in the conductor which, theoretically speaking, forms a store of available force that may afterwards be recovered. (2) There is the period during which the magnet is pulling its keeper to itself, and is positively doing actual work. Now, paradoxical as it may seem, it is a fact that during this period (No. 2), while the magnet is doing actual work, the intensity and the consumption of zinc is actually diminished, so that, in one sense, the more work done the less the fuel (so to speak) which is consumed in doing it. It is in this point that a galvanic battery differs from other machines which do work. It is as if a horse, when he did work, ate actually less food than when he was idle, and wasted less muscle, or as if a locomotive consumed less fuel when in motion than when at rest. (3) Then comes the third period, when the keeper has been pulled home, and the weight is merely sustained. During this period no actual work is being done, and the weight sustained only shows what work the magnet is capable of doing, and so serves as a measure of its potentiality, and during this period (No. 3), strange to say, more zinc is consumed per unit of time than while the work is being done. In practice, therefore, in an electro-dynamic engine, period 3 should be reduced to nil.

Now break the circuit. If there be a secondary wire (as in a Ruhmkorff coil) the tension produced during the first period may be utilised in some way by the counter current produced in thus breaking the circuit, and the same series of phenomena may then begin over again.

What I contend, then, is briefly this (and I will put the matter as distinctly as I can)—that though by lengthening the circuit we prolong the time (period No. 1) which elapses before the magnetic force begins to act, we nevertheless, out of the same consumption of zinc, get an indefinite increase of the force produced. And here let me add that if an electro-dynamic engine were made to act by producing continuous rotation without alternately breaking and closing the circuit, period No. 1 would only come once during the time the engine was at work.

This conclusion of mine may appear paradoxical, but I believe it to be true, both because well-known laws lead logically to it, and because I have found the fact confirmed by experiment. There is one analogous case perhaps still simpler. Take a battery, insert in the circuit a voltmeter with silver electrodes, and containing solution of nitrate of silver. Now separate the electrodes to a distance from each other n times as great as before. This will simultaneously diminish the intensity and the consumption of zinc, but the result will be that the consumption of one equivalent of zinc will convey an equivalent of silver over n times the distance it did before; or if the size of the plates of the battery and of the electrodes be increased severally n times, so as to make the intensity the same as at first, one equivalent of zinc will convey one equivalent of silver n times the distance it did before and in the same time.

One word more, though this letter is already too long. But the subject is important, and it is impossible to be at once full and concise. If the magnetic power of a battery is not illimitable, what is its limit? Let some one give me a reply. The only reply I can find is a statement that the greatest amount of energy is produced in the exterior part of a battery circuit when the exterior and interior resistances

are equal.* Now, in the first place, this can only be true in any case when we do not take into account the amount of zinc consumed, and in the second place it is only true of the heat produced, and it is assumed that all other kinds of energy are in proportion to the heat, than which I venture to say no greater error has ever obtained so wide a credence in an age of critical science. If it were true, all our galvanometers should be formed with short lengths of as thin wire as possible, and our electro-magnets and helices should also be made with very thin and very short wires, which every one knows in practice would be absurd.—I am, &c.,

H. HIGHTON.

Putney, Nov. 22nd, 1870.

PS.—In my letter written to you last week, and in a paper read to the British Association, I maintained that the negative force to be derived from a grain of zinc was without limit.

I gave experiments which proved this, for I showed how a definite force could be got from an indefinitely diminishing consumption of zinc, or an indefinite increase of power from the same consumption.

In fact, my experiments, when I tried them, proved more than this, for, having first found that a battery working a magnet sustained 8 lbs., I made it support 9 lbs. with half the consumption of zinc. I also found an equal consumption of zinc supported 18 lbs. by mere alteration of arrangements. As other people may repeat the experiments and find them fail, I may say that I have since found that the particular alterations of arrangements here described, though answering in that particular case, will by no means answer in all cases. The laws of magnetic power vary so very much in different condition of sizes of wire, dimensions of iron core, and battery strength—conditions which can only be learnt by an immense variety of experiments, that it requires a very special and particular knowledge and experience to apply the particular expedients required under varying conditions.

Nevertheless, in all cases the difficulties may be got over by skill, and the truth, theoretical and practical, remains the same, that the magnetic power of a battery may be increased without limit.

The magnetic power of a circuit is always measured (according to varying conditions) by some power or other of $l \times i$, l being the length of wire outside the battery, and i the intensity of the circuit, and as $l \times i$ may be increased without limit, the magnetic power may be increased without limit. How to vary l and i to the greatest advantage under varying circumstances is the problem which exercises the skill of the engineer. This I may safely say, that never yet has any electro-motor been constructed with a real knowledge of the scientific problem to be solved. I propose shortly to discuss Jacobi's paper on the subject written in 1850 which still remains the great authority, but which is full of errors.—H. H.

PURIFICATION OF SYRUPS.

To the Editor of the Chemical News.

SIR,—Although I am in no way called upon to act as champion for Dr. Seyferth and his process, yet I think it is only right to state that Dr. Calvert, in his letter in your last impression, seems to have misunderstood the claim Dr. Seyferth is putting forth. He cannot, and does not, claim to be the first inventor of a sulphurous acid process for the purification of syrups, for already, as far back as 1849, M. Melsens published such a process, which at once

* I have tried to trace this strange error, which is committed, I find, by Jacobi, De la Rive, Du Moncel, by Professor Foster in the "Chemical Dictionary," and I have no doubt is copied in all our text-books. In some cases I find it deduced from the law of the maximum of heat; in the case of Du Moncel it is due to a most remarkable mistake in an algebraical formula.

raised a great deal of attention on the Continent. In 1858, Dr. Calvert and M. Sievier came out with their plans, and in 1863, the processes of Reynoso, and especially of Possoz and Perier, produced the greatest sensation among German sugar manufacturers. I may safely say that there is not one of the latter class who is not acquainted with this subject, and a gentleman of Dr. Seyferth's attainments would have all these processes at his fingers' ends—among them also Dr. Calvert's, which is quite well known in Germany, as far as published. The feature Dr. Seyferth is claiming as a new one is evidently only the way of employing the sulphurous acid solution, viz., by sucking it up into the vacuum pan along with the syrup; he distinctly states that only by using it in the vacuum pan it can be completely removed again. This seems to be new, and a *prima facie* argument for the real novelty of the process is this, that it has been so warmly recommended by the German Association of Beet-root Sugar Makers, which commands *savans* of the most extensive knowledge of everything published in the matter of sugar making and refining. Without, therefore, taking away from Dr. Calvert's merits, I think Dr. Seyferth has other merits of his own.—I am, &c.,

GEORGE LUNGE.

PRESERVATION OF STONE.

To the Editor of the Chemical News.

SIR,—In his letter which appeared on the 18th of November, Mr. Spiller seems to have completely disposed of his own claim to the superphosphate process, by allowing Coignet's prior use of this method to render a calcareous cement non-absorbent. In both cases the same solution is employed for the same purpose, and with the same result, namely, the conversion of calcium carbonate into tricalcic phosphate by means of a solution of monocalcic phosphate. I take for granted, from Mr. Spiller's silence on the point, that he has abandoned his solution of superphosphate mixed with a little baryta, the really original part of his method.

The legal questions as to patents which Mr. Spiller raises I do not feel to be within my province to discuss.—I am, &c.,

A. H. CHURCH.

Royal Agricultural College, Cirencester,
November 28th, 1870.

MISCELLANEOUS.

The Royal Society.—The annual meeting of the Fellows of this Society was held on the 30th ult., at Burlington House. The President, Lieut.-General Sir Edward Sabine, K.C.B., &c., delivered the inaugural address, in which he reviewed the progress which had been made in science during the year. In closing his address Sir E. Sabine announced his intention not to offer himself for re-election at the next anniversary, when, to quote his words, he "will deliver over the chair, doubtless to a younger, it may well be to a worthier, occupant; it can hardly be to one having the welfare of the Royal Society more warmly at heart,"—a sentiment which was cordially echoed by all present. The presentation of the medals followed:—The Copley Medal was awarded to Mr. James Prescott Joule, F.R.S., for his experimental researches on the dynamical theory of heat; a Royal Medal to Professor William Hallowes Miller, Foreign Secretary R.S., for his researches and writings on mineralogy and crystallography, and his scientific labours in the restoration of the national standard of weight; a Royal Medal was also awarded to Mr. Thomas Davidson, F.R.S., for his works on the recent and fossil Brachiopoda, more especially his series of monographs in the publications of the Palaeontographical Society; the Rumford Medal to M. Alfred Olivier Des Cloizeaux, for his researches in mineralogical

optics. The following gentlemen were then elected officers and council for the ensuing year:—President, General Sir Edward Sabine, R.A., K.C.B., D.C.L., LL.D.; Treasurer, Mr. William Spottiswoode, M.A.; Secretaries—William Sharpey, M.D., LL.D.; Mr. George Gabriel Stokes, M.A., D.C.L., LL.D.; Foreign Secretary, Professor William Hallowes Miller, M.A., LL.D. Other member of the Council:—George Burrows, M.D.; Mr Heinrich Debus, Ph.D.; Peter Martin Duncan, M.B.; Sir Phillip de M. Grey-Egerton; Professor George Carey Foster, B.A.; Mr. Francis Galton; Mr. John Peter Gassiot, D.C.L.; Joseph Dalton Hooker, C.B., M.D.; Mr. William Huggins, D.C.L., LL.D.; Professor George M. Humphry, M.D.; Mr. John Gwyn Jeffreys; Sir John Lubbock; Mr. Charles William Siemens, D.C.L.; Professor Henry J. Stephen Smith, M.A.; Professor John Tyndall, LL.D.; Professor Alexander W. Williamson, Ph.D. After the meeting the Fellows and their friends, including Mr. Gladstone and the Lord Chancellor, dined at Willis's Rooms, the President occupying the chair.

The Purification of Paraffin.—The Mineral Oil Company (Mineralöl Verein), of Halle, in Prussia, offer two prizes of 5000 thalers for the solution of the two following technical questions. The one is, to find a chemical means of purifying crude pressed cake paraffin with the least possible loss, which must not exceed 5 per cent. The other is, to devise a method for cooling masses of paraffin to a temperature of at least 5° C. at any season of the year. Among the materials for the purification of the press cake, colourless oil of tar, benzol, and all like substances which exercise a solvent action on paraffin, are forbidden to be used. The loss of paraffin, when press cake free from dirt is operated on, must not exceed 5 per cent; the process of purification must be rapid and easy of application, and must not be attended with any considerable cost. The refined paraffin is to have a bluish-white colour, and must be colourless. The process for cooling masses of paraffin must admit of 500 cwt. of material being cooled each day, in vessels containing 5 cwt. each, to a temperature of at least 5° C., the cooling to take place either in one place or several. It would be preferable for this to be brought about by cooling the room in which the paraffin candles are left to crystallise. The cooling of the material must be brought about gradually, and in such a manner that the formation of crystals, in respect to their constitution and magnitude, be in nowise interfered with. The answers must be sent in by the 1st January, 1871, and they will be considered by a commission appointed by the Mineral Oil Company of Halle, and composed of Mr. Riebeck, of Halle; Bergrath Bischoff, of Weissenfels; Dr. Rolle, of Gerstewitz; and Dr. Hübner, of Zeitz. In the event of competition, the prize will be awarded to the proposer of the most advantageous solution to the question.—*Journal of the Society of Arts.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Polytechnisches Journal von Dingler, second number for October, 1870.

This number contains the following original papers and essays relating to chemistry and collateral sciences:—

New Aneroid Barometer for the Barometrical Determination of Heights.—J. Goldschmidt.—This paper contains the description, illustrated by a series of engravings, of an improved and accurate

aneroid barometer, which is better fitted for the measurement of mountain heights and elevations above sea level generally.

Convenient Alteration in the Arrangement of Bunsen's Galvanic Battery.—Dr. D. Laschneff.—This paper, treating on an improved arrangement of Bunsen's galvanic battery, cannot be usefully abstracted without the reproduction of a series of engravings.

Description of an Apparatus Contrived for Exhausting Substances.—F. R. von Schwind.—This paper, illustrated by a series of woodcuts, contains the detailed description of an improved apparatus contrived for the purpose of extracting salts soluble in water from insoluble or more difficultly soluble materials.

Enamelling of Iron.—Dr. E. M. Dingler.—The author first points out that the main difficulty in the process of enamelling iron consists in the fact that the expansion of the metal by any increase of temperature is far greater than the expansion of glassy bodies, and that, as a consequence, the enamel is very liable to come off by a sudden increase of the temperature of the enamelled metal. This defect, says the author, is best mended by the use and application of a ground, or first layer, which does not become quite fluid by heat, but retains a pasty consistency and porosity, which enable it to give way to some extent by the expansion. On this first layer, the second, or covering layer, is applied. The author recommends the following mixture as ground or first layer:—Pulverised quartz, 30 parts; borax, 10; white-lead, 3 parts. These ingredients are fused together, and the molten mass is pulverised and intimately mixed with 9 parts of very finely ground-up quartz, 53 parts of washed pipe-clay, and 4 part of magnesia alba. The second, or covering layer, is prepared by melting together a mixture of 37½ parts of pulverised quartz, 27½ of borax, 30 of oxide of tin, 15 of carbonate of soda, 10 of nitrate of potassa, and 5 parts of magnesia alba. The molten mass is poured into water, and afterwards mixed with 64 parts of powdered quartz, 38 of oxide of tin, 4 of carbonate of soda, and 2 parts of magnesia alba, and the whole of the ingredients very finely ground along with water, so as to constitute an impalpable powder. The metal to be enamelled is first cleaned with dilute sulphuric acid (1 part of strong acid to 24 of water), then rubbed with sharp sand, rinsed in hot water, and immediately afterwards dried; the enamel masses are next burnt on. Well made enamel exhibits the following characteristics:—A perfectly smooth and level surface, so that the surface nowhere feels uneven or rough to the touch; a pure white colour; absence of small cracks.

Contribution to our Knowledge on Chlorimetry.—Dr. C. Winkler.—This very lengthy essay records a series of experiments instituted by the author to test the accuracy of Dr. R. Wagner's method of the estimation of chlorine contained in bleaching-powder (hypochlorite of lime); also as compared with the methods of MM. Penot and Mohr. The method of Dr. R. Wagner is based upon the decomposition of a certain volume of a solution of hypochlorite of lime, by means of the addition thereto, first, of iodide of potassium, and next of dilute hydrochloric acid, and estimation of the quantity of iodine set free by means of a titrated solution of hyposulphite of soda. Dr. Wagner recommends to take 1 grm. of hypochlorite of lime to 100 c.c. of water, 2.5 grms. of iodide of potassium dissolved in 25 c.c. of water, and to add dilute hydrochloric acid until an acid reaction is apparent (this method is described at length in Dr. Dingler's *Polytechnisches Journal*, vol. clii., p. 146, 1859). The exhaustive researches of the author of this paper prove that this method is, when executed with care, very correct in its results and thoroughly reliable in practice.

Abnormal Behaviour of Mahrenberg Magnesite.—Dr. H. Schwarz.—While engaged in making some experiments on the manufacture of the Sorel magnesia cement (viz., calcined magnesite mixed with a solution of chloride of magnesium), the author applied for that purpose the magnesite of Mahrenberg (Styria); but, finding that it did not become a hard mass, he analysed this mineral, and found it to contain, in 100 parts—Carbonate of magnesia, 92.52; carbonate of lime, 3.55; carbonate of protoxide of iron, 3.79; insoluble sand, 0.14. At first, the author ascribed the non-hardening of this magnesite, after having been calcined, to the presence therein of carbonate of lime and oxide of iron; but, on making an experiment with amorphous magnesite from Friedau, which contains, after calcination, 2.38 per cent of lime and 0.43 per cent of oxide of iron, it became evident that these impurities did not interfere with the hardening. The author explains the difference by the fact that the Mahrenberg magnesite is a crystalline substance, and stands to the Friedau and Frankenstein magnesites (both amorphous, and the latter especially a very pure material) in the same relation as calc spar (Iceland spar) to arragonite, a view which was proved to be correct by taking the specific gravities of the various magnesites alluded to.

On Wocheinite.—Dr. H. Schwarz.—Under the above name, derived from a locality in Austria, the author gives an account of some experiments made with a hydrate of alumina found in the Wochein, and akin to the Bauxite. This wocheinite consists, in 100 parts, of—Alumina, 56.82; silica, 11.28; peroxide of iron, 1.60; water, 24.20; traces of carbonate of lime and of manganese. The mineral is suitable for being mixed with other fire-clays (it is not sufficiently plastic by itself even when pulverised), and for the manufacture of aluminates of soda and other salts of alumina.

Manufacture of Chromate of Potassa.—Dr. H. Schwarz.—After referring, at some length, to the well-known method of the preparation of chromate of potassa on the large scale, the author relates a few laboratory experiments made with the view to test whether there is any necessity for using, as is usual on the large scale, sulphate of potassa along with the chromate of iron and lime. The result of the author's experiments is, that, when a mixture is made of 1 equiv. of oxide of chromium and 2 equivs. of lime, and these substances very intimately mixed and heated in a muffle, there is obtained a bright yellow-coloured powder, which contains as much as 85 per cent of the oxide of chromium used in the state of chromic acid. The author comes to

the conclusion that the sulphate of potassa is not necessary in the mixture during ignition, and that the chromate of lime formed during the ignition may be advantageously decomposed by bisulphate of potassa, according to the formula—

Decomposition of Chloride of Potassium by Sulphate of Magnesia.—Dr. H. Schwarz. This paper contains the record of a series of experiments made with the view to elucidate the various reactions and formation of double salts which are observed to take place when equivalent proportions of chloride of potassium and sulphate of magnesia are mixed together, having been previously dissolved separately in water. In the first place, there is formed, under these conditions, the well-known potassa-magnesia double salt. This salt having been re-crystallised from a quantity of water, insufficient for its solution, the author obtained (1) a residue of pure sulphate of potassa, containing 46.07 per cent of sulphuric acid, instead of 45.42, as required by theory; (2) the solution yielded on first crystallisation, $\text{K}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 6\text{aq}$, containing, in 100 parts, 39 per cent of sulphuric acid; (3) the second crystallisation yielded a salt wherein the sulphate of magnesia predominates, and consisting, in 100 parts, of 25.12 of sulphate of potassa, 36.21 of sulphate of magnesia, and 38.65 of water, of which 32.49 per cent is eliminated at 100°, and 5.66 by ignition.

Acid Nature of the Organic Matters present in River and Spring Water.—F. Stolba.—The author states that, according to his experience, obtained by making (in Bohemia) a large number of water analyses, all waters which contain a large proportion of organic matter contain it in combination with bases, chiefly lime, and that, therefore, the organic matter is (as already suggested, and partly experimentally proved by Berzelius) of an acid nature.

Simple Method of Detaching Paint and Lacquer-Work from Tinned Iron.—Dr. H. Emsmann.—This method consists virtually to the use of mercury, or of a piece of wash-leather impregnated with that metal, after a slight portion of the paint or lacquer has been first removed from the tinned iron by mechanical means.

Preparation of Condensed Milk.—Dr. Trommer.—A lengthy essay on this subject, but not suited for useful abstraction.

Artificial Formation of Graphite.—Dr. R. Wagner.—After briefly alluding to some reactions by which the origin of native graphite might be referred to the decomposition of cyanogen compounds, and stating that the black mass often observed as the result of the slow and spontaneous decomposition of hydrocyanic acid is, after having been boiled with nitric acid, found to consist of a graphitoid body, the author first directs attention to the formation of graphite in the blast-furnace process, and next states that M. Max Schaffner, director of the chemical works at Aussig (Bohemia), has succeeded in preparing graphite, fit for the making of lead-pencils, as a by-product of the manufacture of soda as carried on by Leblanc's process, the graphite being, in this instance, due to the splitting-up of the cyanide of sodium in a peculiar manner.

Loss of Weight Platinum Crucibles Suffer by being Continually Ignited.—Dr. F. Stolba.—The author has made a series of experiments on this subject, the results being that the rougher and more unpolished the surfaces of platinum crucibles are, the more readily they are acted upon by the flame of well-made Bunsen-burners, because the rough unpolished surface promotes the formation of a compound of carbon and platinum, which is partly consumed by the flame, partly mechanically carried upwards in the hot current of air, after having been detached from the crucible. The author found, by experiment, that, when a good platinum crucible was heated for twelve hours continually, it lost 0.010 grm. in weight, and its surface appeared as if etched, or as the well-known *moire metalique*. This loss and alteration are not due to the presence and subsequent elimination of osmium, because the loss is greater of the crucible than the quantity of osmium contained in crude platinum. The brighter and more polished the surface of platinum crucibles and other platinum vessels exposed to ignition is kept, the better they will resist the deleterious action of the flame.

Simple Method of Obtaining Sea-Sand Fit for Cleaning and Polishing Platinum Crucibles.—Dr. F. Stolba. Since the author resides at Prague (Bohemia), where, of course, sea-sand is not a material readily procured, he came upon the idea of applying to a sponge merchant, requesting him to beat some sponges and collect the sandy matter. In this way the author contrived to obtain a small quantity (some few drachms) of sea-sand, which he cursorily states to consist of about 80 per cent of carbonate of lime and 20 per cent of pure quartzose sand.

Behaviour of Silico-Fluoride of Potassium with the Blow-pipe-Flame.—Dr. F. Stolba.—This salt, exposed to the blow-pipe-flame on a piece of platinum wire, fuses at a moderate heat to a bead, which, while hot, is transparent, but becomes enamel-like on cooling. Continued heating causes the evolution of fluoride of silicon, whereby the bead shrinks, and yields, after cooling, a clear, transparent glass, which, having been qualitatively tested, was found to consist of fluoride of potassium and of silicate of potassa. The bead alluded to is, says the author, a very suitable substance for blow-pipe tests. Silico-fluoride of sodium does not yield a transparent bead at all.

Analysis of Alabaster Glass.—Dr. F. Stolba.—This glass was that of a broken lamp-shade. It was very hard, and contained in 100 parts—Silica, 52.3; alumina, 3.2; lime, 3.3; potassa, 3.66; soda, 5.60. Fluorine, oxide of tin, phosphoric acid, and arsenic acid were not present.

Crystallisation of Chlorate of Potassa by Fusion.—Dr. F. Stolba.—When a tolerable quantity of this salt is cautiously fused in a large platinum crucible, and after being slowly cooled, the surface,

previous to its becoming quite solid, is pierced with a piece of thick platinum wire, and the still fluid mass poured out, the crucible will be found lined with crystals, which, according to the author, are of the same shape as those exhibited by the salt when crystallising from its aqueous solution.

Analysis of a Peat-Ash from Benatek (Bohemia).—Dr. F. Stolba.—The peat alluded to leaves from 20 to 22 per cent of ash, consisting, in 100 parts, of—Soluble in hydrochloric acid: Sulphate of lime, 20.15; carbonate of lime, 17.27; caustic lime (Aetzkalk), 22.4; magnesia, 0.47; alumina and oxide of iron, 13.35; sulphuret of calcium, 0.74. Insoluble in hydrochloric acid: Lime, 0.84; magnesia, 0.06; alumina and peroxide of iron, 3.62; silica, 19.79; water and carbonaceous matter, 10.1.

Precaution to be taken when Paraffin is Applied as a Means of Preventing the Boiling Over of Fluids.—Dr. F. Stolba.—Since paraffin has very little, if any, affinity at all for acid and alkaline fluids, it is often used to prevent, in chemical operations, the boiling over of liquids. The author states that, while engaged in preparing sulphurous acid gas by heating copper turnings and strong sulphurous acid, he used paraffin to prevent that mixture (very apt to boil over in consequence of the tumultuous evolution of gas) from boiling over; but, after awhile, an explosion took place, caused by the fact that the gas delivery-tube had become choked by the paraffin, which in molten state had been mechanically carried over by the sulphurous acid gas, and on cooling in the gas delivery-tube, stopped the exit for the gas, and thus caused the destruction of the apparatus. In case, therefore, paraffin is used in such operations, the gas delivery-tubes should be wide, and the operator should pay attention if any paraffin becomes deposited in the tube.

Manufactory of Peas-Pudding Sausages (Erbswurst) at Berlin.—Dr. Dingler.—It appears that a Berlin cook, named Grünberg, has recently discovered a process by which a preparation of peas may be made so as to keep without becoming sour, and the Prussian Government has bought the secret of this process from the inventor, for a sum of £5555. The Prussian War Office has created an establishment, at Berlin, capable of producing daily 75,000 sausages made of this preparation, which consists of a mixture of bacon, peculiarly-prepared pea flour, onions, and other ingredients, inclusive of salt. The sausages are sent away packed in boxes containing from 100 to 600, weighing 1 lb. each, which are destined as food for the armies, and only requiring to be boiled in water for a very short time to be ready for the use of the soldiers. The daily ration of each being 1 lb., a quantity quite sufficient for each man. This establishment, only working for the armies, costs daily about £6000.

Zeitschrift für Chemie von Beilstein, No. 16, 1870.

This number only contains one original paper:—

New Method of Quantitative Analysis.—H. Carmichael.—As far as it is possible without the reproduction of a number of woodcuts, essentially necessary for the proper comprehension of the contents of this paper, we will try to give an account of the author's method of analysis. In the introduction to his paper, the author animadverts upon the fact that, on an average, the results of per centually-quoted analysis, made by experienced analysts, vary from 99.17 to 100.67, a difference of 1.5 per cent; or, when 1.5 grm. has been taken and weighed off, and the weighings during the operations been carried to 0.0001 grm., a variation of 225 units. As to the causes of these irregularities, the author states that they are chiefly, if not solely, due to the manipulations, among which decantation is one of the principal sources of error. The author then proceeds to describe, and illustrates by woodcuts, a series of ingeniously-contrived apparatus, the object of which, chiefly, is to render such operations as decantation, filtration, drying, and ignition of substances, readily and very accurately-executable operations, the author states that even a couple of milligrams of substance are sufficient for a complete analysis. The paper contains the following example of an analysis made by the author's method:—

	Quantities weighed off.	Found.
MgO	0.0690	0.0688
KCl	0.1873	0.1852
NaCl	0.0876	0.0900
	0.3439	0.3440

Without having seen this method, and the apparatus required, it is difficult to judge of its merits. It is very probable, however, that, if the author's process is found to answer as well as he leads us to believe, the apparatus will soon be obtainable from the dealers in such articles, who are generally men well enabled to judge whether a novelty will become generally available for use.

American Journal of Pharmacy, November, 1870.

This number contains the following original papers and memoirs relating especially to chemistry and allied sciences:—

Pulverisation of Camphor.—W. Procter.—It is well known that camphor is easily reduced to powder by rubbing with a few drops of alcohol, but the powder so made will, after a short time, aggregate to crystals, which have to be rubbed down again. The author mixes with the powder of camphor so obtained, carbonate of magnesia, 10 grains to the ounce being sufficient; this powder never cakes or forms crystals.

Crystallisation of Sulphocarbonate of Quinine.—Dr. C. J. Rademaker.—Crude sulphocarbonic acid was saturated with plumbic carbonate, the sulphocarbonate of lead crystallised and decomposed with sulphate of quinine, the solution of sulphocarbonate of quinine filtered and evaporated, but it was found almost impossible to crystallise the salt, owing to the gelatinous condition of part of the solution, which adhered to the small amount of crystals formed; the gelatinous mass was re-dissolved in alcohol, but with no better result as regards the obtaining of crystals. The author then made a solution of definite strength, and obtained, after a length of time (some few weeks), large crystals of prismatic shape, which on analysis were proved to be sulphocarbonate of quinine, a salt freely soluble in water, not deliquescent, and but slightly soluble in alcohol.

Amount of Arsenic in the Phosphorus of Commerce.—Dr. C. J. Rademaker.—Since the author had frequently to prepare dilute phosphoric acid, according to the directions given in the U. S. P., he states that he always takes the precaution of passing a current of sulphuretted hydrogen through the solution, in order to free it from all substances precipitable by that agent from acid solutions, the result always being that by this operation sulphide of arsenic is thrown down; in order to estimate the amount thereof, 100 grms. of phosphorus were oxidised with nitric acid, the solution diluted, and the arsenic precipitated as sulphide, As_2S_3 , by means of sulphuretted hydrogen; the solution was allowed to rest for six days, after which the precipitate was collected on a filter and washed, transferred to a small evaporating dish oxidised with nitric acid, reduced by means of sulphurous acid to arsenious acid, again precipitated, but in the form of As_2S_3 , by means of sulphydric acid, the precipitate digested with ammonia to free it from adhering sulphur, the solution filtered, evaporated, dried, and weighed, and found to amount to 15 grains, or nearly 1 gramme of sulphide of arsenic.

Sulphocarbonate of Zinc.—Dr. A. B. Lyons.—The author first prepares crude sulphocarbonic acid by heating together 17 parts of strong sulphuric acid with 16 of carbolic acid; this mixture having been diluted with 10 times its volume of water is saturated with carbonate of lead; into the filtered solution of sulphocarbonate of lead, a quantity of pure granulated zinc, equal in weight to the carbolic acid employed, is introduced; at the end of 24 hours the solution will be usually found free from lead, giving no precipitate with sulphuric acid or potassium iodide; when the solution is in that condition it is decanted, heated to boiling, filtered, and evaporated to a small bulk to crystallise; the salt so prepared is quite free from sulphate, and yields fine large crystals free from any empyreumatic odour.

Solubility of Glue in Glycerine.—J. M. Maisch.—This paper contains a lengthy account of some experiments instituted by the author, who was called upon to act as expert in a suit involving the right to manufacture a composition for printing rollers in which sugar is wholly or partially substituted by glycerine, and since one of the attorneys (*Anglice*, "barrier"), engaged by one of the parties to the suit, stoutly denied the solubility of glue in glycerine, and said that this was the result of experiments made, the author set to work, and the results of his carefully made experiments may be summarised as follows:—Glue is soluble, at the ordinary temperature, in a large proportion of glycerine; glue is permeable by glycerine, slowly at ordinary, more readily at an elevated, temperature; glue swelled in consequence of the absorption of water remains unchanged in appearance under glycerine, that is to say, even if the glycerine should abstract the water, the former will take the place of the latter liquid, thus preventing the shrinking of the glue; glue, by continued digestion, dissolves completely in glycerine, gelatinising on cooling; the solution of glue in glycerine is accelerated by previous maceration in glycerine, and by increasing the temperature, and doubtless also by pressure; glue thoroughly permeated by water dissolves in hot glycerine about as readily as it does in hot water. The author throws out the valuable hint, that the property of gelatine of being soluble in glycerine might be turned to account to prepare a well-keeping standard solution of gelatine to be used for the assay of tannin-containing substances, since the aqueous solution of gelatine becomes very soon spoiled by standing after having been made.

NOTES AND QUERIES.

University of Giessen.—"Vox" wishes to know where he can ascertain the course for obtaining degrees at the University of Giessen.

Alkaline Fluorides.—I should feel greatly obliged if you would inform me how the solutions of neutral fluorides of the alkalis are made, as I want the above to etch glass with. In looking over past numbers I cannot find anything that treats of them.—O. X. O.

Dextrine—Lactic Acid.—(Reply to "Carbon.")—To estimate the quantity of dextrine in a solution likewise containing glucose, Dr. Gentile determines the total amount of these bodies by means of a standard solution of potassio-cupric-tartrate, and then estimates the glucose with an alkaline solution of ferricyanide of potassium (red prussiate) which does not act upon dextrine; the difference of the two determinations gives the quantity of the dextrine. Consult the article on "Dextrin" in Dr. Watts's "Dictionary of Chemistry," vol. ii., p. 312, and following. The tests for lactic acid, which are, however, not very definite, you will find fully described in Dr. Miller's "Elements of Chemistry," 4th edition, vol. iii., p. 415. Our space will not allow us to transcribe the passages.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 5th.—London Institution, 1. Dr. Odling, F.R.S., "On Chemical Action." (Educational Course.)
— Medical, 8.
— Royal Institution, 2. General Monthly Meeting.
TUESDAY, 6th.—Institute of Civil Engineers, 8.
— Zoological, 9.
WEDNESDAY, 7th.—Society of Arts, 8.
— Geological, 8.
— Pharmaceutical, 8.
THURSDAY, 8th.—London Institution, 7.30. W. Mattieu Williams, F.C.S., "On Count Rumford and his Philosophical Work."
— Royal, 8.30.
— Royal Society Club, 6.
FRIDAY, 9th.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

* * Vol. XXI. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 7s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each post free, may also be obtained at the Office.

A Subscriber from St. Petersburg.—The second part of the work is not yet published; it will be duly announced.

J. B. Barnes.—Received.

S. E. P.—The letter is too complicated for our pages.

St. Bartholomew's Hospital.—The LECTURESHIP OF CHEMISTRY in the Medical School of this Hospital being vacant, Gentlemen desirous of offering themselves as Candidates are requested to send their Applications and Testimonials to the undersigned on or before Friday, the 9th December next.

WM. HENRY CROSS, Clerk.

St. Bartholomew's Hospital.

November 22, 1870.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870—1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c. All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXII. No. 576.

SPECTROSCOPIC NOTES.*

By Prof. C. A. YOUNG, Ph.D.,

Professor of Natural Philosophy and Astronomy in Dartmouth College.

A New Form of Spectroscope.—The instrument, a description of which follows, was designed for attachment to the equatorial of 6.4 inches aperture and 9 feet focal length, belonging to the observatory of Dartmouth College. It is specially intended for observations upon the solar spots and protuberances, and accordingly the principal object kept in view has been to combine a very high degree of power with compactness, lightness, facility of manipulation, and firmness and construction. Having the dispersive power of 13 prisms of heavy flint, each with an angle of 55°, it yet weighs less than 15 pounds, and measures over all 15 inches in length, 8 in breadth, and 4½ in height. It was made by Alvan Clark and Sons.

The accompanying plate (Fig. 1), taken from a photograph, gives a correct idea of its appearance and general arrangement. The collimator and observing telescope have each an aperture of 7ths of an inch, and a focal length of 7 inches, which might advantageously have been increased to 12 inches were it not for the necessity of compactness.

The light from the slit after passing the collimator, is transmitted through the lower portion of a train of six prisms of heavy flint glass, each 2½ inches high, and having, as stated above, a refracting angle of 55°. A seventh half-prism follows, and to the back of this is cemented a right angled prism by which, after two total reflections, the light is sent back through the upper part of the same train of prisms, until it reaches the observing-telescope. This is placed directly above the collimator, and firmly attached to it. Finally, a diagonal eye-piece brings the rays to the eye in a convenient position for observation.

The instrument thus has the dispersive power of thirteen prisms, and even with the low magnifying power of only five on the observing-telescope, shows perfectly the lines of aqueous vapour, which make their appearance between the sodium lines when the sun is near the horizon. Of course, everything shown on the maps of Kirchhoff and Angstrom is readily seen with it, and many lines besides.

Its definition is very beautiful, and the only optical fault of the instrument seems to be a curvature of the lines, resulting from the shortness of the collimator.

After planning the instrument, I learned that the same idea of sending the light twice through the prisms by a right-angled prism at the end of the train had also occurred to Mr. Lockyer and others; but I do not know that it has yet been put in practice elsewhere.

The prisms, for protection and convenience of handling, are set in frames of blackened brass. They are arranged around the circumference of a hollow cylinder of elastic gun-metal, 3½ inches in diameter, with stout flanges above and below, between which they are clamped by little

thumb-screws, so that they can be readily removed or transposed: it requires less than a minute to put the last prism with its reflector in place of any other of the train, thus reducing the dispersive power to any extent desired.

No particular care is required in placing the prisms, as a couple of narrow flanges were cast upon the cylinder near the top and bottom, and afterwards planed off to form true bearings for the backs of the prisms. They are thus always correctly set by being simply slid home before tightening the clamping screws.

The lower flange of the cylinder is attached to the base-plate by a screw directly under the middle of the front face of the first prism. Around this point as a centre the whole system of prisms is movable by means of a double threaded tangent-screw which brings the different portions of the spectrum into the field of view.

FIG. 1.

The adjustment of the prisms to their angle of minimum deviation is effected by a method devised by Mr. George Clark, which is exceedingly simple, and, if not theoretically exact, answers every practical purpose. The flanges between which the prisms are clamped, are sawed through between the prisms, and a portion of the cylinder, flanges and all, equal to an arc of about 30°, is cut out between the first prism and the last. On closing up or spreading open this gap by means of a suitable tangent-screw, the circumference of the circle around which the prisms stand is correspondingly enlarged or diminished. Probably, when the ends of this opening are drawn very near together, or spread very far apart, the cylinder is somewhat distorted, and a corresponding mal-adjustment of the prisms results; but if so the effect is very slight.

The instrument gives a perfect view of every part of the spectrum A to H: above *h*, however, when all seven prisms are used, there is a loss of light occasioned by a partial obstruction of the apertures of the collimator and telescope by the corner of the reflecting prism.

Were it important to secure the perfect cylindricity of the prism-frame through the whole range of adjustment, it could be easily done by merely fastening at the back of each prism a radial bar acting upon a central pin as in the arrangement first devised by Mr. Rutherford, and since adopted by Mr. Browning in his automatic spectroscope.

* From advance-sheets of the *Journal of the Franklin Institute*. Communicated by the Editors.

This plan of Mr. Clark's, doing away with all joints and hinges, has the great advantage of perfect firmness and solidity in every position of the instrument, an advantage hardly to be overrated in an astronomical spectroscope.

Had it occurred to me in season I might have made the instrument still simpler, firmer and perfectly automatic in its adjustment, by merely substituting for the first prism a *half prism*,* like the last of the train, to which the right-angled reflecting prism is cemented.

Placing this first *half prism* with its front face perpendicular to the line of collimation it would never need to be disturbed; the flange of the cylindrical frame which carries the prisms would be firmly fastened to the bed-plate immediately beneath it, and the pivot joint at this place with the corresponding tangent-screw would be dispensed with. The only adjustment required would be that produced by the screw which is now used to adjust for minimum deviation by opening or closing the gap of the cylinder.

Of course this arrangement would reduce the dispersive power of the train by the amount of one prism, a loss easily made up by adding a degree or two to their refracting angles.

Fig. 2 exhibits the plan of the proposed arrangement, and requires no explanation, unless to remark that, for

the sake of distinctness, I have represented only two of the radial bars which may be used to render the adjustment accurate.

It might be better to place the face of the first prism not exactly normal to the line of collimation, in order to avoid repeated reflections between it and the object-glass of the collimator, which would be likely to produce a troublesome ghost, or the same thing might be accomplished by simply cementing the object-glasses of both collimator and observing-telescope, directly upon the front of the prism; this would make the instrument still more solid and compact.

The eye-piece of the instrument has an apparatus attached, which, however, thanks to the high dispersive power, I find unnecessary.

It was early proposed by Janssen to use a vibrating or rotating slit in order to make visible the form of a solar prominence, but as Zöllner has shown, the mere opening of the slit answers just as well, the light of the protuberance being diluted to precisely the same extent in either case.

It occurred to me, in connection with a suggestion of Professor Morton, that by interposing at the focus of the eye-piece a diaphragm which should move with the vibrating slit, the light of the neighbouring portions of the spectrum might be cut off and this dilution avoided. Mr. Clark has devised and constructed a very beautiful mechanical arrangement by which this simultaneous and accordant motion of slit and diaphragm is effected by the rotation of the small fly-wheel shown in Fig. 1.

But I find, that although seen in this way, the prominences appear very bright; yet the working of the apparatus always causes a slight oscillation of equatorial, which interferes with the definition of details, and I prefer to work with the slit simply opened. When the air is free from haze, the whole extent of a prominence 30,000

miles in height is readily examined through the C or F line, and the most delicate details reveal themselves, with a beauty and clearness of definition which even yet always surprises me, and speaks most emphatically for the exquisite workmanship of the 43 different surfaces by which the light is either refracted or reflected on its way from the slit of the collimator to the eye.

But, although I do not use the vibration of the slit and diaphragm, I find the mobility of the slit so convenient as to be practically indispensable. In examining the spectrum of a group of sun spots, for instance, it is very much easier to move the slit to the particular point we wish to observe than to move the solar image by the tangent screws of the equatorial.

Photographs of the Solar Protuberances.—The protuberances are so well seen through the F and 2796 (near G) lines, that it is even possible to photograph them, though, perhaps not satisfactorily with so small a telescope as the one at my command. Some experiments I have recently made show that the time of exposure, with ordinary portrait collodion, must be nearly four minutes, in order to produce images of a size which would correspond to a picture of the solar disc about 2 inches in diameter. This length of exposure demands a more perfect clockwork than my instrument possesses, and a more accurate adjustment of the polar axis than it had during the experiments, as well as a steadier condition of the atmosphere.

Thus far, therefore, I have not been able to produce anything which could properly be called a good picture. Negatives have been made which show clearly the presence and general form of protuberances, but the definition of details is unsatisfactory. This amount of success was reached upon September 28th, when impressions were obtained of two protuberances on the S.E. limb of the sun, and, slight as this success was in itself, I consider it of importance in showing the perfect feasibility of going much further with more sensitive chemicals, more delicate adjustments, and greater telescopic power. I was aided in the experiments by Mr. H. O. Bly, our local photographer, to whom are due my warmest acknowledgments for the interest, patience, ingenuity, and skill with which he assisted me.

We worked through the hydrogen γ line (2796 of Kirchhoff's scale), which, though very faint to the eye, was

found to be decidedly superior to F in actinic power. The photographic apparatus employed consisted merely of a wooden tube, about 6 inches long, attached at one end to the eye-piece of the spectroscope, and at the other carrying a light frame. In this frame was placed a small plate-holder, containing, for a sensitive-plate, an ordinary microscope slide, 3 inches by 1. The image of the prominence, seen through the open slit, is magnified and thrown upon this plate by the eye-piece. Fig. 1 shows the instrument with this apparatus attached.

It would be easy to improve this arrangement in many respects, and whenever I resume the subject I propose to do so.

As the equatorial, however, has been dismantled, to be put in order for the observation of the December eclipse, further attempts in this direction must be postponed until next spring.

* On returning from the Eclipse Expedition my instrument will be made automatic in accordance with this plan.

Observations of the Solar Protuberances.—Without prolonging this article with the detail of observations, I add a few of the results which have been obtained since September 10th.

About forty different prominences have been more or less carefully observed: sixteen have been sketched. Most of them fall, naturally enough, into the categories established by Zöllner and Lockyer, and are fairly represented by figures already published.

A few deserve especial mention, however. Fig. 3 represents a small one, which was observed upon the E. limb of the sun on September 14th, about 4.30 p.m. From the point marked A, which was very brilliant, a small fragment detached itself and rose towards A', enlarging in size and growing fainter as it rose. It disappeared (from faintness) in about twelve and a half minutes, at a distance of 2' 30" above the limb of the sun, as determined by the time, 8' 5", which was occupied by the intervening space in passing over the slit of the spectrocope. Allowing for the

obliquity of the motion to the parallel of declination, the length of path passed over by this cloud was more than 90,000 miles, and the velocity above 120 miles per second.

Fig. 4 represents a prominence observed September 20th, at 4 p.m., on the S.E. limb. (Pos. S., 60° E.) It was a nearly vertical stream, made up of spindle-formed filaments, and had attained the enormous height of 3' 20", or 90,000 miles (determined, as in the case above-mentioned, by a time observation, corrected for inclination). It was very brilliant near the base, and at two or three other points along its length. At 4.30 it was nearly gone, only a few faint wisps of cloud remaining.

Another, observed on September 27th, at 4.10 p.m., and situated on the W. limb of the sun, is represented in Fig. 5. It was formed of separate, well-defined narrow

streamers, which appeared to consist of matter, first violently ejected, and then as violently deflected, by some force acting nearly at right angles. The altitude of the highest point was 1' 25", the length of the whole about 3' 30". I am unable to see how any mere projection from the sun could have produced such a form, and cannot help feeling that it indicates a *something* in which powerful currents may exist, even at such great elevations above

the solar surface; in short, an atmosphere extending far beyond the limits which calculation would seem to assign as possible. Is it wholly unlikely that, at such an enormous temperature, the law of Mariotte may fail so completely as to destroy the reliability of any computation that assumes it as one of the data?

Upon the next day the prominence still persisted, but the type was wholly changed: it was replaced by one of the mushroom-formed masses which are so common.

Bright Lines.—In the spectra of different protuberances, the following bright lines have been observed, the numbers referring to Kirchhoff's scale: C; D₁; D₂; D₃; 1474; 1515; b₁; b₂; b₃; b₄; 1990; 2001; 2031; F; 2581.5; 2796; h—17 in all. On one occasion, September 27th, the base of a prominence on the N. W. limb, close to a spot just leaving the limb, exhibited as many as twelve or fifteen short bright lines between E and F, which are not included in the above enumeration, as I had not time to identify them. It is the only instance in which I have seen this phenomenon, more than once described by Mr. Lockyer.

I desire to call special attention to 2581.5, the only one of my list, by the way, which is not given on Mr. Lockyer's. This line, which was conspicuous at the eclipse of 1869, seems to be *always present* in the spectrum of the chromosphere, and shows the form of its upper surface or of a protuberance nearly as well, though of course not so brightly, as the 2796 line. It has no corresponding dark line in the ordinary solar spectrum, and not improbably may be due to the same substance that produces D₃.

The reversal of the sodium and magnesium lines is not at all uncommon. In some instances these lines were so bright, that on opening the slit the form of the prominence could be made out through them. This was the case with a small hand-shaped prominence observed on September 27th. Comparing the form thus seen through D₁ and D₂, with that given by D₃, it appeared that the sodium line was sufficiently developed for observation only along the edge and at one or two bright points in the prominence, most brilliantly neither at its summit nor its base. Fig. 6 represents the appearance

(the slit was perpendicular to the sun's limb). The case was similar with the magnesium lines.

Spectrum of Solar Spots.—Several spots have been carefully examined at different times, most of them, in their spectra, gave evidence of unusual disturbances; but by far the most interesting phenomena were exhibited by a large group which was first observed near the E. limb on September 19th. Changes of wave length were frequent in its neighbourhood.

Figs. 7 and 8 represent the appearances assumed by the F and C lines respectively, at the times indicated below each figure, during an observation on the afternoon of September 22nd. The point where these changes of wave-length occurred was at the western edge of the penumbra. At other times similar changes were observed, but not so great or rapidly varying.

The calcium and titanium lines referred to in my note, published in the July number of the *Journal of the Franklin Institute* (CHEMICAL NEWS, vol. xxii., p. 218), were always conspicuously thickened in the nucleus spectrum.

The C and F lines were reversed in some portion or other of the group nearly every time I observed it. On September 22nd, the sodium lines were both reversed for several hours, while D₃ appeared as a dark shade. On September 28th, again, at 4 p.m., the southern nucleus of

the group (which at this time contained four large umbrae, besides many small ones), reversed all of the following lines, viz.: C; D₁; D₂; D₃; 1474; b₁; b₂; b₃; b₄; F; 2796; and h. All of these were conspicuous, except 1474; D₃ and b₃ especially so, and the latter (a nickel

line) showed considerable changes of wave-length, alternate increase and diminution, which were not shared by its magesian neighbours, b₁, b₂, and b₄.

At 4.05 p.m. the brilliance of the F line increased so greatly that it occurred to me to widen the slit, and to my great delight I saw upon the disk of the sun itself a brilliant cloud in all its structure and detail identical with the protuberances around the limb. Indeed, there were two of them, and there was no difficulty in tracing out and delineating their form. Fig. 9 represents them as they

were from 4.05 to 4.10; Fig. 10 gives the form at 4.15-20. They were then considerably fainter than at first. During the intervening ten minutes I examined the other lines of the spectrum, and found that the form could be distinctly made out in all the hydrogen lines, even in h;

but that the reversal of the other lines, including D₃, was confined to the region immediately over the spot-nucleus, where the smaller but brighter cloud terminated abruptly; or, I might better say, originated. The larger one faded out at both ends. When the clock-work of the equatorial was stopped, the luminous cloud took 16.7 seconds of

time to traverse the slit which was placed parallel to the hour-circle. This indicates a length of at least 130,000 miles without allowing anything for the foreshortening resulting from the nearness of the sun's limb.

By 5 o'clock the clouds had nearly disappeared; a little rack alone remained.

At 4.20 I examined the spot with the equatorial, using the ordinary solar eye-piece. Nothing remarkable was to be seen—not the merest trace of the enormous masses of incandescent gas. It will be interesting to learn whether the earth responded to this magnificent eruption on the sun by any magnetic storm.

I may add that in the telescope this group of spots, from their first appearance, exhibited a strong yellowish tinge, which appeared to overlie all the central portion of the cluster. So conspicuous was it that several persons, unaccustomed to astronomical observation, noticed it at once before I called their attention to it. The penumbra of the group was unusually faint.

Hanover, N.H., October 3rd, 1870.

ON THE NUCLEAR ACTION OF A SALINE CRYSTAL ON A SUPERSATURATED SOLUTION OF THE SAME SALT.

By CHARLES TOMLINSON, F.R.S.

BEFORE attempting to reply to the second part of Mr. Liversidge's paper (p. 253 *ante*), I must call upon him to get rid of what seems to me to be an illogical distribution of his argument, which I now proceed to expose.

I state that cold supersaturated solutions of *magnesian sulphate* were kept for some time over sulphuric acid in an exhausted receiver, when crystalline crusts of the normal salt were formed on the surface, and that these, by shaking, fell through the solution without acting as nuclei.

Mr. Liversidge replies to this statement by quoting one of Löwel's experiments on *sodic sulphate*, accompanied by Löwel's remark that "it is not the normal salt which is formed in allowing a supersaturated solution to evaporate spontaneously under cover, but the modified salt or that with seven atoms of water."

Mr. Liversidge remarks that such crystals are inactive, "which inactivity seems to be only explicable by accepting Löwel's analyses."

Now, granting for the moment, the relevancy of Löwel's experiment, I want to have it made clear to my understanding, that because *sodic sulphate* behaves in a certain manner, under certain conditions, *magnesian sulphate* must also behave in the same manner, under the same conditions.

I have no opportunity of consulting the reference to Löwel's first memoir without going into town, but my impression is that Löwel's experiment was not made for the purpose of determining the nuclear action of the modified *sodic sulphate* salt, but expressly for determining its hydration. All through this first memoir he accepts Faraday's analysis, and calls it the 8-atom salt; but in a *Note additionelle* he describes an experiment in which a boiling solution of *sodic sulphate* was placed, in company with *calcic chloride*, under the receiver of an air-pump, and kept there for days, and, if I mistake not, for weeks, until the whole of the liquid part had evaporated. Then from the lower part of the mixed crystalline mass he selected crystals from which he determined the hydration of the modified salt.

It will be seen from this statement, supposing it to be correct, that Löwel's experiment leads to a very different result compared with that in which crystalline crusts are formed on the surface of a long column of a supersaturated solution.

When a supersaturated solution of sodic sulphate is set aside and left undisturbed for weeks and months the liquid portion diminishes slightly in volume and crystalline crusts are formed in the neck of the flask just above the solution. This effect is best obtained by using a globular flask with a long, straight, cylindrical neck, a portion of which is occupied by the solution. On inclining the flask the solution may be made to wash over these crystals, and even to wash them down, when, in the latter case, they fall slowly through the solution, but in no case do they act as nuclei. I showed an experiment of this kind to a distinguished Fellow of the Chemical Society a few weeks ago. The flask had been kept on a window-ledge during some months: on inclining it the crystals in the neck were washed down, and they fell to the bottom of the solution without any nuclear action. On taking out the cotton-wool crystallisation of the normal salt immediately set in from the surface.

Solutions of magnesian sulphate are well adapted to the exhibition of this class of phenomena, as the crystals not only creep up the neck, but form on the surface, and both results are produced much more quickly than in the case of sodic sulphate.

Ammonium-phosphate also forms clear crystalline crusts in the neck of vessels containing supersaturated solutions of that salt. I have kept the solution in contact with the crust for days together without any perceptible kind of action. In order to see whether the crust was corroded by contact with the solution, I traced an outline of the crust in ink on the outside of the tube before bringing the solution into contact with the crust. After several days' contact I could not find any diminution in the magnitude of the crust or in the sharpness of its outline. Of course the solution, being supersaturated, could exert no solvent action on a salt of its own kind, just as in washing out the remaining colouring matter from a cone of refined sugar a saturated solution of white sugar is passed through the mould; it washes the sugar without dissolving it.

Now, in order to reduce the subject of this note to a practical issue, I have to propose two questions to the gentlemen who have opposed my views (whom, I beg to say, I regard not as opponents, but as friends and coadjutors in the pursuit of truth).

I. Are not the crystalline crusts that form in the neck of a vessel containing a supersaturated solution of sodic sulphate constituted like the normal salt with ten atoms of water?

II. Are not the crusts that form on the surface of long columns of a supersaturated solution of magnesian sulphate and creep up the neck of the vessel constituted like the normal salt, with seven atoms of water?

Unless these questions can be clearly and distinctly answered in the negative on the indisputable grounds of experiment and analysis, then I contend that the general proposition that the best nucleus that can be employed for bringing about the crystallisation of a supersaturated saline solution is a crystal of its own kind, is not true.

Highgate, N., December 5th, 1870.

On page 265, col. 2, line 29 from bottom, for "the surface-tension of the solution was lowered," read *increased*.

ON THE COMPARATIVE INFLUENCE OF VARIOUS SUBSTANCES IN PREVENTING THE DECOMPOSITION OF ORGANIC SUBSTANCES.

By Dr. F. CRACE CALVERT, F.R.S.

ON reading the interesting article by Dr. Sansom, in your issues of the 18th and 25th ult., on "Evidence Concerning the Germ Theory of Fermentation afforded by the Action of Certain Substances when Suspended in the Air," it occurred to me that it might prove of some service to

many of your readers if I were to lay before them the results of a series of experiments I made some eighteen months ago, to ascertain the comparative powers of various substances ordinarily used as antiseptics.

Before entering into the details of the experiments, I would remark that there is a considerable confusion in the use of the terms antiseptic, disinfectant, and deodoriser, against which it is well to guard. A deodoriser is a substance which removes unpleasant or noxious odours; a disinfectant one which prevents the spread of infection; and an antiseptic one which prevents the substance with which it is in contact from entering into a state of fermentation or putrefaction. As examples of deodorisers may be mentioned chloride of manganese and sulphate of the protoxide of iron. Among antiseptics are chloride of mercury, chloride of zinc, chloride of sodium, arsenious acid, some of the essential oils, carbolic acid, and cresylic acid. Disinfectants are of two classes—those which act by oxidation, destroying the organic substances which give rise to the infection (such as permanganate of potash, bleaching powder, and nitric acid); and those which act, as Dr. Sansom shows, by their presence, undergoing no decomposition themselves, but appearing to poison or render innocuous the germs of disease. To this class belong camphor, and sulphurous and carbolic acids. Of course all the substances above mentioned do not possess exclusively the properties of the class to which I have referred them, but I believe that their predominant characteristic is that which I have assigned them.

With a view of carrying out the statement made in the first paragraph, I made two distinct series of experiments; the first consisted in placing in bottles (not corked) solutions of albumen and flour paste. To these I added various proportions of some of the substances patronised at the present time as antiseptics, and the following table shows the results obtained:—

Antiseptic employed.	Percentage of antiseptic.	Time in which it acquired an offensive odour. Temperature from 70° to 80°	
		Albumen.	Flour-paste.
McDougall's disinfecting powder ..	5	11 days	25 days
Carbolic disinfecting powder	5	{ Remained sound	Remained sound
Chloralum (made lately)	2	9 days	—
Chloride of zinc ..	2	15 days	—
Chloride of lime ..	5	16 days	14 days
Permanganate of potash	5	—	—
Tar oil	2	11 days	25 days
Carbolic acid ..	2	{ Remained sound	Remained sound
Cresylic acid ..	2	{ Remained sound	Remained sound
None	—	5 days	7 days

The above table clearly shows that the only true antiseptics are carbolic and cresylic acids, and these results coincide with those obtained by Mr. William Crookes, F.R.S., Dr. Angus Smith, F.R.S., and Dr. Sansom. For these two acids continued their action till the albumen solution and paste dried up.

It follows that if deodorisers are merely required for removing the noxious odour from any mass of matter in a state of decay or decomposition they may be used with advantage; such are chloride of manganese, chloride of lime, sulphate of iron, permanganate of potash, chloralum. But if it is desirable to prevent the decomposition of organic matter (and, in my opinion, this is the point to be aimed at, for prevention is better than cure), then carbolic and cresylic acids are the only two substances which attained this object.

As the products given off from decaying organic matter are well known to facilitate the decomposition of similar classes of substances to themselves, if placed in close

proximity (no doubt by the atmosphere conveying the germs), I made the following experiments with the view of ascertaining which of the undermentioned substances would possess the most active power in destroying such germs, and thus preserving the animal substance from decay. At the bottom of wide-mouthed pint bottles I placed a known quantity of each of the antiseptics, and suspended over them by a thread a piece of sound meat, and, by daily examination, it was easily ascertained when the meat became tainted or putrid. The following table gives the results obtained:—

Antiseptic used.	Became tainted.	Putrid.
Potassium permanganate	2 days	4 days
Chloralum	2 "	10 "
McDougall's disinfecting powder	12 "	19 "
Chloride of lime	14 "	21 "
Tar oil	16 "	25 "
Chloride of zinc	19 "	—
Carbolic disinfecting powder	Did not become tainted, but dried up and became quite hard.	
Carbolic acid		
Cresylic acid		

ABSTRACT OF A PAPER ON THE

ABSORPTION OF SULPHUR BY GOLD, AND ITS EFFECTS IN RETARDING AMALGAMATION.*

By WILLIAM SKEY,

Analyst to the Geological Survey of New Zealand.

THE author of this paper, while recently investigating the causes of the reported loss of gold during the process of extraction at the Thames Gold Fields, observed that much of this loss could scarcely be referred to any of those causes generally supposed operative for it. He therefore tested the actual condition of the natural surfaces of numerous specimens of Thames gold, in respect to their behaviour with mercury, and examined, further than has hitherto been done, into its comportment with several of those substances likely to be associated with it in a natural way.

The results of these examinations have been minutely recorded in this paper, while the following is a short abstract of them:—

The author finds—

(1.) That numerous samples of bright, clean-looking gold, of all degrees of fineness, refuse to amalgamate on any part of their natural surfaces, though taken directly from the reef and untouched by hand.

(2.) That on such surfaces sulphur is always present.

(3.) That native gold, or gold in a pure state, readily absorbs sulphur from moist sulphuretted hydrogen or sulphide of ammonium, and absorbs it directly when administered in boiling water.

(4.) That surfaces so treated refuse to amalgamate, though no apparent change can be observed in their aspect.

(5.) That gold so affected is rendered amalgamable by wasting in an open fire, except copper is present to the extent of seven per cent (or perhaps less), while the same effect is produced by the contact of cyanide of potassium, chromic and nitric acid, and chloride of lime acidified.

(6.) That this absorption is altogether of a chemical nature.

(7.) That sulphates of iron in presence of air and water decomposed various metallic sulphides common to auriferous reefs, in such a manner as to liberate sulphuretted hydrogen.

The action of sulphuretted hydrogen upon gold, in rendering it non-amalgamable when placed in contact with mercury, was demonstrated with striking effect by the author before the members of this Society.

From these results the author has been led to suppose that a large area of the natural surfaces of native gold is covered with a thin film of an auriferous sulphide, and that the greater part of the gold which escapes amalgamation at the battery is represented by that portion of this sulphurised gold which has remained unabraded during the processes of milling or extraction from the reef; the state of the gold, rather than that of the mercury, therefore, being the greatest impediment to thorough amalgamation.

In addition to these results, the author communicated others, relative to the effect of solutions of sulphuretted hydrogen and sulphide of ammonium upon platinum. In rendering it non-amalgamable, he believed a sulphide of the metal had formed in each case, since chromic acid rendered it again amalgamable. He also stated that this metal is also so affected by ammonia or the fixed alkalies that it will not amalgamate, except in presence of a mineral acid; from which he suspects platinum is capable of superficial oxidisation when in contact with alkaline substances, even at common temperatures.

The author found that his samples of gold were not affected by the alkalies in this manner, except in the case of one from Victoria, a singularity from which was argued the presence of palladium in this particular sample.

ON LIQUIDS OF HIGH DISPERSIVE POWER.

By WOLCOTT GIBBS, M.D.,

Rumford Professor in Harvard University.

OF the liquids which have hitherto been proposed for the construction of prisms, bisulphide of carbon unquestionably presents the greatest advantages. It is cheap, colourless, and unites a moderately high mean refractive to a very high dispersive power. By tacit consent, a prism of 60° filled with this liquid has come to be adopted as a sort of standard. The disadvantages of the bisulphide are equally well known, and I have spent no little time and labour in the endeavour to find a liquid with a still higher dispersive power, less volatile, less sensitive optically to changes of temperature, and less offensive in odour. In these efforts I have not been altogether successful, no one liquid examined possessing all the qualities desired. Many organic liquids with high dispersive powers are difficult to prepare in a state of purity, and speedily become discoloured by absorption of oxygen from the air. Such are oil of cassia, the colourless oil obtainable from balsam of Peru and others. The thallic alcohol of Lamy* is far too costly. The solution of silico-tungstate of sodium†, of meta-tungstate of sodium‡, and of soluble tungstic acid§ as obtained by dialysis, all promised good results from their extraordinary densities, but all proved difficult to prepare in a state of purity, and extremely easy of decomposition.

A solution of phosphorus in bisulphide of carbon, has, according to Messrs. Dale and Gladstone||, a dispersion of 0.225¶, or nearly one and a half times as great as bisulphide of carbon alone, but becomes turbid on exposure to sunlight from the formation of amorphous phosphorus. It occurred to me that, by dissolving sulphur with the phosphorus, the formation of amorphous phosphorus might be prevented, and experiment proved that this was the case. The solution, as thus obtained, has a pale yellow colour, but is perfectly clear, and undergoes no change by the action of light even when long continued. I have been in the habit of preparing it by dissolving 1 part of dry flowers of sulphur and 2 parts of phosphorus in 4 or 5 parts of bisulphide of carbon, and filtering the

* Read before the Wellington Philosophical Institute, September 17th, 1870.

liquid through a well-dried ribbed paper filter, which is easily done. The refractive and dispersive power of the solution will, of course, vary with the quantity of phosphorus and sulphur dissolved. By a gentle heat, the whole, or nearly the whole, of the bisulphide of carbon may be driven off, a liquid compound of sulphur and phosphorus remaining, which has so high a mean refractive power that it cannot be employed with prisms having a refractive angle of more than 45° – 50° . The same end may, however, also be attained by continually adding phosphorus to a saturated solution of sulphur in bisulphide of carbon, in which phosphorus appears to be soluble without limit.

With a strong and probably saturated solution of sulphur in CS_2 , the angle between Li and D was $0^{\circ} 50' 10''$. When phosphorus was added, the angle was $2^{\circ} 25' 30''$, the refracting angle of the prism being 60° . In this last case the angle between Na_1 and Na_2 was $0^{\circ} 2' 20''$. The spectrum was perfectly clear, the definition of the dark lines leaving nothing to be desired. In consequence, however, of the yellow colour of the liquid there is always a marked absorption of the violet end of the spectrum.

In working with the above-described solution, I have employed hollow glass prisms with refracting plates cemented on with a mixture of glue and molasses. These were found to be perfectly tight, and to last for months without change. The great disadvantage in the use of a solution of sulphur and phosphorus consists in the danger of breaking the prisms; the liquid taking fire spontaneously when it has been a few seconds in contact with any porous material like wood or paper. On the other hand, however, the large quantity of sulphur present prevents the fire from spreading, a drop placed upon a piece of wood leaving, after combustion, only a charred spot. When not in use the prisms should be kept in an iron pot with a tight cover. In this manner I have employed and preserved two during a long and hot summer. The viscid, or rather oily, nature of the solution serves to prevent, to a great extent, the formation of ascending and descending currents from slight changes of temperature; and, when the prisms are well shaken before use, the definition remains perfect for a long time. In my spectroscopie, the prisms rest upon a plate of glass instead of upon one of metal.—*American Journal of Science.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 1st, 1870.

Professor WILLIAMSON, F.R.S., President, in the Chair.

THE following gentlemen were elected Fellows:—H. E. Armstrong, Ph.D.; R. Barklie; W. L. Carpenter; T. M. Crafts, Professor of Chemistry in Cornell University; J. Dewas; T. Farries; R. Mallet, F.R.S., and Dr. Ogg.

Mr. PERKIN, F.R.S., read a paper "On Some Derivatives of Anthracene." This was a detailed account of some anthracene derivatives, more particularly of the products resulting from the action of sulphuric acid upon dibrom- and dichloranthracene.

Dichloranthracene.—It is most conveniently prepared by passing chlorine gas over benzol, holding about one-fifth its weight of purified commercial anthracene in suspension, until the mixture becomes a crystalline mass. The product is then brought on a linen filter, drained, washed with cold benzol, dried, and then further purified by distillation and subsequent re-crystallisation from benzol. Thus obtained it appears in golden-yellow needles. The mean of several analyses gave 67.91 per cent C, 3.34 per cent H, and 28.70 per cent Cl,

which numbers agree perfectly with the formula of Græbe and Liebermann, $\text{C}_{14}\text{H}_8\text{Cl}_2$.

Dichloranthracene, when gently heated, sublimes in beautiful needles, which may be obtained of considerable size. It is fluorescent in the solid state as well as when in solution.

When a boiling solution of dichloranthracene in benzol is added to a similar solution of picric acid, the mixture assumes a dark orange-red colour, and on cooling becomes filled with small bright red needles. These consist of a compound of dichloranthracene and picric acid. A determination of the dichloranthracene in this body gave numbers closely approximating to those required by the formula—

Dibromanthracene.—This product was prepared by Græbe's process. It was, however, purified first by distillation and then by crystallisation from benzol. Thus obtained it is of a golden-yellow colour. It gave on analysis numbers closely agreeing with those required by the formula—

Like dichloranthracene this body produces a beautiful red compound with picric acid.

Action of Sulphuric Acid on Dichloranthracene.—Dichloranthracene, when submitted to the action of fuming sulphuric acid, dissolves, forming a bright green solution, and is at the same time converted into a sulpho-acid.

To prepare this acid, one part of dichloranthracene is added to about five parts of fuming sulphuric acid, and the mixture heated for a short time on the water-bath. It is then gradually poured into several times its bulk of water and treated with carbonate of barium until all the sulphuric acid is neutralised. The acid solution when filtered off from the sulphate of barium is evaporated to a small bulk. When sufficiently concentrated, it becomes, on cooling, a shiny mass of minute orange-yellow-coloured crystals, which may be drained on a porous tile.

This acid has not been analysed, but from the composition of its salts evidently possesses the formula—

Mr. Perkin therefore proposes to call it disulphodichloranthracenic acid. It is easily soluble in water, from which it is precipitated upon the addition of a little concentrated sulphuric or hydrochloric acid. It possesses a strongly acid taste and character.

The acid forms salt with sodium, barium, calcium, and strontium. The barium salt is remarkable for its insolubility in hydrochloric acid.

Dibromanthracene yields with strong sulphuric acid an analogous disulphodibromanthracenic acid—

Its sodium, barium, &c., salts are similar to the salts of disulphodichloranthracenic acid.

Oxidation of Disulphodichlor- and Disulphodibromanthracenic Acid.—These sulpho-acids, when subjected to the influence of oxidising agents, rapidly decompose, exchanging their chlorine or bromine for oxygen, and are thus converted into disulphanthraquinonic acid.

An analogous result is also obtained by treating them with concentrated sulphuric acid, the following reactions taking place:—

Anthracene, when pure in large crystals, shows a beautiful fluorescence, and so do many of the anthracene products, though curiously their solutions are comparatively poor in this respect. Anthracene and dichloranthracene in the state of vapour are not at all fluorescent, and, moreover, a ray of light sent through the length of about four inches of the vapour of either body still retained its power of rendering fluorescent bodies luminous.

The experiments in this direction are, however, not yet concluded. On sealing up anthracene in a long vacuum-tube with platinum poles, and allowing the discharge from an induction coil to pass through the tube, nothing particular is observed except the beautiful fluorescence of the crystals of anthracene. On examination with the spectroscopic, the light showed carbon and nitrogen lines, the latter arising from the presence of a little air in the tube. Upon heating the tube, however, somewhat strongly, so as to volatilise the hydrocarbon, the ordinary colour of the discharge changed to a magnificent deep azure blue, and what is remarkable is that this blue light, when examined with the spectroscopic, is perfectly continuous, and consists of blue with a little green.

Dichloranthracene, when treated in a similar manner gives an analogous result, but suffers a good deal of decomposition, anthracene changing but little. These curious results do not appear to be due to the fluorescent character of the substances employed, as naphthalene produces a similar effect, the blue light, though not so intense, being continuous. It must be observed, however, that this hydrocarbon undergoes considerable change, becoming brown and oily.

Anthracene, heated in a vacuum-tube in the same way, gives a greenish blue light, showing faint carbon bands.

On exposing a solution of disulphodichloranthracenic acid to the light of one of the recent displays of the Aurora Borealis, it was very strongly illuminated, as might be expected. Moonlight, on the other hand, had no perceptible effect upon it, nor yet an alkaline solution of esculine.

Mr. Perkin illustrated his interesting communication by a series of most beautiful experiments.

The society then adjourned to December 15th.

LONDON INSTITUTION.

On Thursday, the 1st inst., Professor MORRIS, of University College, delivered a lecture "On Gems and Precious Stones," in which the science of the mineralogist, chemist, and geologist, was combined with the industrial lore of the miner, lapidary, diamond-cutter, and agate-stainer. Having glanced at the different systems of classification adopted by mineralogists, the lecturer noticed the distinctive physical characters of the substances known as precious stones, calling special attention to the crystalline form, cleavage, hardness, and refractive power of the diamond. He stated that the diamond was the only representative among gems of the elementary bodies. It was a form of carbon, and, under certain conditions, it could be readily burned into carbonic acid gas. A curious calculation showed that the great Koh-i-noor if burned would furnish just enough gas to charge from twelve to fourteen bottles of soda-water. The optical properties of the diamond had led Newton to regard it as a combustible body long before the actual combustion of the gem had been effected. The dull varieties of the diamond known as "carbonado"

and "boort" were largely used in the arts, for steel-engraving, glass-cutting, rock-boring, and other purposes. The mineralogical and geological features of the diamond beds of India, Brazil, Borneo, South Australia, and South Africa were described, and the frequent association of diamonds with itacolumite, gold, and rutile was referred to as a subject worthy of careful investigation. Other precious stones, such as the sapphire, ruby, emerald, beryl, topaz, jargon, garnet, spinel, and turquoise, were treated of successively, reference being made to their chemical composition, their physical properties, and their application to decorative and industrial purposes. Artificial gems, "doubles" made of glass, faced with slices of the real stones, and artificially coloured agates were noticed, and the characters by which they might be distinguished were plainly indicated. The lecture was illustrated by a valuable and interesting collection of objects. Messrs. Blogg and Martin contributed a unique series of uncut diamonds, exhibiting perfect crystalline forms, some large diamonds from South Africa, and one remarkable specimen embedded in the "cascalio" from a diamond bed in Brazil. Professor Tennant contributed a large collection of diamonds in the natural state, and also some curious specimens of quartz that had been mistaken for diamonds. Through the kindness of Messrs. Hunt and Roskell, the lecturer was enabled to exhibit a fine series of gems and models of the great South-African diamond before and after cutting. To Mr. James Gregory, again, the lecturer was indebted for a collection of ornamental minerals, models of most of the famous diamonds, and specimens of the gravel and rocks associated with the diamonds in South Africa.

On Monday afternoon Dr. ODLING delivered his sixth lecture "On Chemical Action." The circumstances modifying combustion were discussed and illustrated by a remarkable series of experiments with the oxyhydrogen blowpipe, and the hot and cold blast.

NOTICES OF BOOKS.

Die Spectralanalyse in ihrer Anwendung auf die Stoffe der Erde und die Natur der Himmelskörper. Gemeinlich dargestellt, von Dr. H. SCHELLEN, Director der Realschule I. O., zu Cöln. Braunschweig: Druck und Verlag von George Westermann, 1870.

The Spectrum Analysis, in its Application to the Matter of the Earth, and to the Elucidation of the Nature of the Heavenly Bodies. A popular treatise, by Dr. H. SCHELLEN, Director of the Realschule I. O., in Cologne. Published by George Westermann, Brunswick, 1870.

THIS is, undoubtedly, the most thorough work on the subject of spectrum analysis which has yet appeared.

Some fifty pages are, in the first place, devoted to the sources of light—such as the oxyhydrogen, the magnesium, and various sorts of electric lights, as well as the common flames and Bunsen burners.

The nature of light, as illustrated by the more readily studied phenomena of sound, and the general laws of reflection, refraction, and dispersion, are then discussed in some fifty more pages.

The spectroscopic is then fully described and illustrated with the phenomena of optical phosphorescence and selective absorption. This portion of the work occupies some seventy pages, and is full of new valuable matter, some of which we shall presently describe more in detail.

Next to this comes the sun spectrum and the Fraunhofer lines, with the discoveries of Bunsen and Kirchhoff, and the observations of Janssen and others as to the aqueous lines. A full discussion of the phenomena of sun spots then follows, profusely illustrated with many new engravings admirably executed. This takes us about fifty pages further.

The solar prominences next receive attention, and here we have a full account of the observations of De la Rue

in 1860, with copies of his photograph, and of all the similar work accomplished in 1868 by Vogel, Tennant, Janssen, and others, as also the discoveries of Lockyer and Huggins. Here, also, are a vast number of the most interesting illustrations, and nearly one-hundred pages are devoted to this subject.

The next hundred pages are devoted to a full description of instruments, methods, and results, in connection with the study of stellar, nebular, cometary, and meteoric spectra; and, lastly, we find a few pages on the spectra of lightning and the aurora.

The entire work is eminently characterised by that thoroughness which is the eminent merit of German treatises, and nothing is alluded to which is not fully explained.

Thus we were disappointed to find in Roscoe's otherwise excellent book on this same subject a figure of Bunsen's apparatus for illustrating selective absorption, which was neither self-explanatory nor accompanied by

any description. Here, however, we find a much clearer figure supplemented with a full account, from which the action of this curious and ingenious arrangement becomes at once manifest.

This is of so much interest that we have reproduced the figure on a smaller scale, and here give it with a sufficient description. A and B are two flasks containing zinc and hydrochloric acid mixed with a solution of salt. The hydrogen evolved is thus filled with a fine spray of salt. Pipes b and b' lead into these flasks the ordinary illuminating gas, which mingles with the salt-charged hydrogen, and escapes by pipes c and c', each of which, by a sort of locomotive exhaust action, carries with it a large amount of air into the pipe above, from which the mixture passes into burners, the first of which, f, is of a scoop shape, and makes a strong flame, which is to serve as the background to the other. By adjustment of the relative amounts of hydrocarbon gas and hydrogen, the flame, g, is made very intense, while d is rendered as cool as possible. By this means the light from g is well absorbed in traversing d, and this later appears as a black flame when seen against g as a background.

Portraits of Bunsen, Kirchhoff, Huggins, and Secchi, in the shape of excellent woodcut plates, are interspersed through the book, which has, besides, two coloured plates and 158 woodcut illustrations, a few of which we have seen before in some of Hachett's publications, but the greater portion are entirely new and of great value.

CORRESPONDENCE.

THE PRESERVATION OF STONE.

To the Editor of the Chemical News.

SIR,—In his last letter to you Mr. Church commences by adducing another argument against the originality of his own proposal, and concludes with the following statement—"The legal questions as to patents which Mr. Spiller raises I do not feel to be within my province to discuss." Perhaps not, but this will have to be done by deputy, as I am advised to dispute the validity of the patent for a "Combined Process," which merely unites your own and my inventions, without any superadded feature of novelty to constitute an independent claim.

During the present year I have upon two occasions applied my superphosphate process, exactly in accordance with the instructions which I gave in the text of a paper "On the Decay of Stone; its Cause and Prevention," read at the Dundee meeting of the British Association, September, 1867, and printed at page 123 of your sixteenth volume. The public should be free to use the mixed mono-calcic and baric phosphates as therein described by me (not patented), and we shall soon know what plea can be raised in support of this recent attempt at monopoly.—I am, &c.,

JOHN SPILLER.

London, December 3rd, 1870.

MAGNETIC POWER EVOLVED BY A BATTERY.

To the Editor of the Chemical News.

SIR,—Last week I said that no electro-motor had ever yet been constructed with a thoroughly scientific knowledge of the elements of the question. Let me justify myself by enumerating these elements—the mutual relations of which, to each other, has never yet been thoroughly investigated. Indeed, thoroughly to investigate them would require a lifetime, and could only be done by large co-operation. They are, then,—

1. The kind of battery to be used.—Strange as it may seem, different kinds of batteries have very different magnetic effects in particular combinations, and laws deduced from the use of one battery cannot be applied to another. The reason, no doubt, is that when the intensity of different batteries varies, the effect of the reactions and polarisations produced in them differ very much. For instance, Bunsen's batteries and Daniell's, if used in the same experiments, give totally different laws.
2. The size of the plates in the battery.
3. The number of cells as producing more or less electro-motive power, but with a consumption of zinc varying as the square of the intensity produced.
4. The size of wire.
5. The shape of wire, whether round, flat, or square.
6. The length of wire and number of ranges of spires on coil.
7. The number of derivations of circuit.
8. The form of construction of magnet, whether bar, horse-shoe, with two, three, or more poles, whether what the French call *aimants boîtes*, &c., &c.
9. The weight and number of magnets.
10. The relation of length to diameter of magnets.

11. The size, shape, and mode of application of the soft iron armatures.

12. The length of stroke.

13. The best kind of commutators.

And finally, and above all, the most beneficial adjustment of each of these in reference to the others.

We have an infinite source of force. Can we avail ourselves of it economically? Even the most essential element of the question, namely, how the magnetic force varies in regard to the intensity (β) and length of current (l), has not yet been decided. *Quot homines, tot sententia*. The prevailing opinion is that the energy varies as $l^2 \times i^2$. Some say that it varies rather as the simple powers than as the squares of these two quantities. My own opinion, formed from the consideration of numerous experiments, is inclined to the conclusion that the energy to be obtained from a current may be made to vary, according to different circumstances, in proportion to almost any powers of l and i , but that if we secured such conditions as should give a maximum of force, the magnetic energy of a battery would be found to vary (nearly, but not quite, as the square of the power of conveying matter by electrolysis, and of the power exercised by a wire over a magnetic needle, namely) as $l^2 \times i^2$. But whether it varies as $l \times i$ or as $l^2 \times i^2$, or as any other powers of l and i , the conclusion remains the same, that $l \times i$, and consequently any power of $l \times i$, may be increased by skill without assignable limit.—I am, &c.,

H. HIGHTON.

Putney, December 5, 1870.

THE REACTION BETWEEN WATER AND NITROGEN TETROXIDE.

To the Editor of the Chemical News.

SIR,—I do not wish to revive in your columns a rather unimportant discussion which arose at the Chemical Society out of some expressions used by Mr. E. T. Chapman in describing a determination of nitric oxide. But as any reader of the brief report sent to you, and of Mr. Wanklyn's comments, who was not present at the discussion, would suppose me to have called in question some familiar and well-established facts, I shall be obliged if you will insert a few lines of explanation.

First, let me repeat what I stated twice in the course of the discussion, that I do not doubt, and have never doubted, the possibility of converting nitric oxide into hydrogen nitrate by the action of an excess of oxygen and water.

Next, as to the only point on which I ventured to differ from Mr. Chapman, and upon which, as far as I was concerned, the discussion turned. What is the reaction which takes place between water and nitrogen tetroxide? Mr. Chapman's view, for which he claimed the authority of a formidable list of text-books, is that these substances react to form hydrogen nitrate and nitric oxide, according to the equation

If this representation were correct, the complete conversion of the nitric oxide into hydrogen nitrate would be almost instantaneous, and would be simultaneous with the disappearance upon contact with water of the red fumes formed on mixing this gas with excess of oxygen.

But, in fact, at the ordinary temperature, and in the presence of much water, when the red fumes have disappeared, the liquid contains not hydrogen nitrate only, but a mixture of nitrate and nitrite in equivalent proportions. The equation representing the change is

Afterwards, by degrees, the hydrogen nitrite is oxidised to nitrate, but so slowly that if, even after some interval, the amount of oxygen that has been absorbed is measured, it is found to be just what is required to form nitrate and nitrite, and less by one-third than the amount required to yield nitrate only.

The rate of the subsequent change depends upon the temperature and concentration of the acid liquid, and probably, also, the nature of the change, since a cold dilute solution may be simply oxidised, as hydrogen sulphite would be oxidised, by the superjacent and dissolved oxygen, while a warmer or more concentrated solution would be partially decomposed with evolution of nitric oxide.

But I see no reason for believing that at any temperature near the ordinary temperature the production of nitrite does not form an integral part of the reaction.—I am, &c.,

A. VERNON HARCOURT.

Christ Church, Oxford,
December 3rd, 1870.

MISCELLANEOUS.

Stone Waterproofing.—At the recommendation of Professor Abel, Chemist to the War Department, the process invented by Messrs. Gay and Co., of Alton, Hants, for waterproofing and preserving stone and other buildings, is, by the order of the Office of Works, to be applied to the decayed stonework of the Houses of Parliament.—*Journal of Society of Arts.*

Precaution to be taken in the use of Phosphorus for the Absorption of Oxygen from Gaseous Mixtures.—Dr. Commaile states that when phosphorus comes in contact with a solution of caustic potassa, even at the ordinary temperature, phosphuretted hydrogen is given off, and if, therefore, phosphorus be employed to absorb oxygen from a gaseous mixture contained in an eudiometer tube or bell-jar, into which previously a solution of caustic potassa had been introduced for the purpose of removing from the said gaseous mixture carbonic acid, the result will be that, if the piece of phosphorus be only wetted by the potassa solution, the quantitative estimation of the bulk of the gaseous mixture will become a failure in consequence of the evolution of phosphuretted hydrogen gas. The author states that a series of experiments made by him prove that the increase in bulk of the gaseous mixture is, even at a low temperature, rather considerable, and at summer temperature, after two or three days, the gaseous mixture, when coming into contact with free air, ignited spontaneously when the piece of phosphorus fastened to platinum wire had dipped for a few millimetres depth into the potassa.

Preparation of Ultramarine Test-Paper.—The great sensitiveness of artificially-made ultramarine for even very weak acids has been turned to account by applying that pigment to prepare a test-paper especially suited for the rapid detection of the presence of free acids in such salts as sulphate of alumina, alum, and other similar compounds. The ultramarine intended for this use should be that known commercially as No. 1; it should first be mixed with some water collected on a filter, and then thoroughly washed with some boiling distilled water, and afterwards incorporated with a mucilage made of 1 part of selected Irish moss, previously washed with cold water, boiled with about 30 parts of distilled water; the pigment thus obtained is uniformly painted over best filtering paper, and, after drying, cut up into strips, as is usual for litmus-paper, and preserved in a glass-stoppered bottle. In order to test the ultramarine, it is necessary to prepare a perfectly neutral alum in the following manner. Alum of commerce, by preference, potash alum, is dissolved in from 8 to 10 times its weight of boiling water, and this solution is poured into twice its bulk of alcohol at 80 per cent. The alum separated after complete cooling is collected, redissolved in boiling water, and the solution again poured into the same quantity of fresh alcohol of the same strength; the alum which separates on cooling is collected on a filter, and, after having been washed with alcohol, dissolved in water; a drop or two of this solu-

tion should not discolour the ultramarine, while its almost instantaneous discolouration should follow on its being touched with a drop or two of very dilute sulphuric acid, 1 part of strong acid to from 50 to 60 parts of distilled water.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, June, 1870.

This number contains the following original papers and memoirs on subjects relating to physico-chemical and collateral sciences:—

Relation Existing between the Hemiedric Crystalline Shape and the Thermo-Electric Properties of Iron Pyrites and Grey Cobalt.—Dr. G. Rose.—This lengthy essay, illustrated by a series of engravings, treats especially on the crystallography of two peculiar kinds of minerals, and on the mode in which the crystalline form affects the thermo-electric properties of these substances. Cobalt glance, or grey cobalt, is a rather rare mineral, found especially in Sweden, and consisting, in 100 parts, of—Sulphur, 20.08; arsenic, 43.46; cobalt, 33.10; iron, 3.23;—total, 99.87.

Reduction of the Annual Curves of Temperature to the Conditions upon which they are Naturally Based.—Prof. Dove.—A meteorological essay.

Contribution to our Knowledge of Meteorites.—C. Rammelsberg.—This very exhaustive memoir contains the following sections:—Analysis of meteorites; separation of nickel from iron; extraction and determination of meteoric iron in such meteorites as are chiefly composed of stony matter; analysis of the silicates; on meteoric iron; on the pallasite from Brahin (Russia); on the chondrites from Poltusk, Richmond, and Iowa. The main result of the author's labours is, that the four chondrites analysed by him only contain two silicates—the mono-silicate, or olivine, and the bisilicate, or bronzite.

Further Investigations on Methyl-Aldehyde.—Dr. A. W. Hofmann.—This paper chiefly contains the results of a comparative investigation instituted by the author to ascertain how far the experiments and views held by M. Aimé-Girard (published in *Comptes Rendus*, vol. lxx., p. 623), on the methyl-aldehyde, are correct, and how far these researches agree with those instituted by the author. In this essay, the author chiefly treats on the sulphuretted methyl-aldehyde, and states that the assumption of a tri-molecular constitution for that substance leads to far more simple formulae than when the constitution of that body is taken to be di-molecular, as has been done by M. Aimé-Girard. There is added to this paper an appendix treating on the—

Sulphaldehyde of the Ethyl Series.—This portion of the paper is devoted to the record of a series of experiments on the vapour density of the sulphaldehyde of ethyl, the formula of which has been usually taken as C_2H_4S . The author, however, finds that the proper formula for this body is $C_2H_4S_2$; its vapour density, as compared with hydrogen gas, is 90, and as compared with air, 6.25. The author states that there exists an undoubted analogy between sulphmethyl-aldehyde and the sulphaldehyde of the ethyl series, but there is a great difference between the ethyl-metalddehyde and the metalddehyde of the methyl series. The vapour density of metalddehyde, C_2H_4O , was found to be 22 as compared with hydrogen, and 1.52 as compared with air.

July, 1870.

Aromatic Cyanates.—Dr. A. W. Hofmann.—The author refers briefly to his discovery of the body now named phenyl-cyanate; at the time of its discovery (about twenty years ago) it was called anilonic acid. This substance is obtained when the diphenyl-carbamide is heated with phosphoric acid, but this reaction is not suited for its preparation in large quantities. While engaged with his experiments on the essential oils of mustard, the author thought that the decomposition of phenyl-urethan might be turned to account for the preparation of phenyl-cyanate. When phenyl-urethan is treated with methylic, ethylic, or amylc alcohols, there are formed phenyl-urethans of the methyl, ethyl, and amyl series. The phenyl-carbaminic acid ether yields, when heated, although a portion escapes decomposition, alcohol and phenyl-cyanate, $C_6H_5NO = C_6H_5NO_2 + C_2H_4O$. When phenyl-urethan is heated with anhydrous phosphoric acid, phenyl-cyanate is obtained in larger quantity. The distillate is a volatile liquid, boiling at 163°; its vapour is irritating to the eyes; sp. gr. at 150°, 1.092; vapour density, as compared with hydrogen, 59.5, as compared with air, 4.13. When a glass rod, moistened with triethyl-phosphine, is immersed into phenyl-cyanate, much heat is evolved, and the entire mass becomes solid, exhibiting beautiful crystals. The author then gives a

description of some homologues of phenyl-cyanate, and among these is tolyl-cyanate, a liquid which has a strong refractive power and an irritating smell; it boils at 183°; vapour density, as compared with hydrogen, 66.5; as compared with air, 4.61. The tolyl-cyanate exhibits, with triethyl-phosphine, the same reaction as the phenyl-cyanate. Xylol-cyanate, obtained from xylol-urethan, is a liquid boiling at 200°; vapour density, as compared with hydrogen, 73.5, as compared with air, 5.10. Naphthyl-cyanate, obtained from naphthyl-urethan by distillation with anhydrous phosphoric acid, is a heavy colourless liquid, nearly inodorous at the ordinary temperature, and boiling at about 270°; formula—

Journal für Gasbeleuchtung, October, 1870.

On Hydrotimetry.—M. Grabn.—This paper contains a detailed description of a method for the quantitative determination, by volumetric analysis, of the mineral substances in water. Titrated solutions of soap, oxalate of ammonia, nitrate of baryta, and nitrate of silver are used. This method of analysis was first proposed by MM. Boutron and Boudet, and has been chiefly employed in France for testing the water supplied by the water companies, for whose use it is especially adapted.

Application of Coke as Fuel for Domestic Purposes, and on the Best Construction of Stoves for Coke.—A. Buhe.—This long paper, which is illustrated with a series of engravings, contains a series of interesting experiments on the combustion of coke; the vitiation of air in rooms by its combustion; the best mode of constructing the stoves, and on the most convenient size of the fuel. For stoves and kitchen fire-places, the author considers that it would be desirable for gas-works to sell the coke, broken up, by means of properly constructed machinery, into lumps about the size of walnuts.

Water Supply of Paris.—Dr. N. H. Schilling.

New Project of Water Supply for Berlin.—Dr. N. H. Schilling.

Annalen der Chemie und Pharmacie, October, 1870.

The original papers relating to chemistry are the following:—

Constitution of Phloridzine.—H. Schiff.—The author first alludes to the action of dilute acids upon phloridzine, $C_{21}H_{33}O_{10}$, which is thereby split up into glucose and phloretine. This latter substance is, when acted upon by a boiling solution of caustic potassa, split up into phloretinic acid and phloro-glucose. The paper further contains a detailed account of the proper formula for denoting the constitution of phloretine, of which the two following formulae are given:—

To ascertain which of these two formulae is the most trustworthy, the author instituted a series of experiments for the purpose of testing the mode of combination of phloretine with acetyl, by acting on the former body with chloracetyl or acetic anhydride. He also describes the mode of preparation, properties, and constitutional behaviour of the following bodies:—Diacetyl-phloretine, $C_{24}H_{36}O_{12} = C_6H_5O_2 + H_2O$; pentacetyl-phloridzine, $C_{24}H_{36}O_{12} = C_6H_5O_2 + H_2O$; triacetyl-phloridzine, $C_{21}H_{33}O_{10} = C_6H_5O_2 + H_2O$; acetyl-phloridzine; caramel of phloridzine; acetyl-rufine; phloridzin-anilide; phloretin-anilide; mono-acetyl phloridzin-anilide; triacetyl phloridzin-dianilide; tribenzoyl-phloridzine.

Hydrate of Protoxide of Nickel.—H. Teichmann.—The author has studied the behaviour of the protoxide of nickel with ammonia and with carbonate of ammonia. He first calls attention to a fact, which, he says, is not mentioned in any work on chemistry—viz., that when the protoxide alluded to is precipitated from its saline combination at the boiling-heat of the aqueous solution, the resulting precipitate retains acid which cannot be removed by a continuous washing with water, but the precipitate obtained from nitrate of nickel becomes, after long-continued washing, freed from acid; and if other salts of the protoxide of nickel are employed, the impure precipitated hydrated protoxide is readily purified by dissolving it in ammonia to which a small quantity of a salt of that base has been added.

On Chromate of Protoxide of Nickel, and on the Double Chromate of Protoxide of Nickel and Ammonia.—E. A. Schmidt.—This paper treats chiefly on the labours of MM. Freese, Malaguti, Sarzeau, and others, on the salts just named. The author has made a series of analyses which prove that the formula of chromate of protoxide of nickel is $3NiO \cdot CrO_3 + 6H_2O$, and not, as stated by M. Malaguti and others, $4NiO \cdot CrO_3 + 6H_2O$; but the salt is only formed as long as the protoxide of nickel is in excess, for, when the chromic acid prevails, a salt of the following composition, $5NiO \cdot 2CrO_3 + 12H_2O$, is formed. The formula of the double chromate of nickel and ammonia is—

Action of Ammonia on a Chloro-Propionic and on β Iodo-Propionic Acid.—W. Heintz.—This essay is divided into the following sections:—Behaviour of ammonia with ethylen-chloropropionic acid; behaviour of ammonia with ethylen-iodopropionic acid; behaviour of alcoholic ammonia with ethylen-iodopropionic acid; behaviour of aqueous ammonia (liquid ammonia) with ethylen-iodopropionic acid.

Diglycolamide Nitrate of Silver.—W. Heintz.—After first referring to his researches on the combination of diglycolamide and nitric

acids, the author states that diglycolamide nitrate of silver is analogous in composition to diacetamide nitrate of silver. The former body is a crystalline salt, exhibiting a rhombic shape, insoluble in alcohol and water, and decomposed by heat, leaving metallic silver. Composition, in 100 parts:—Carbon, 11.71; hydrogen, 1.46; silver, 52.68; nitrogen, 6.83; oxygen, 27.32. The author also describes the lead and copper salts of diglycolamide-nitric acid.

Double Phosphate of Oxide of Copper and Soda.—J. Weineck. —This paper reviews the labours of Dr. Kammelsberg on some salts of phosphoric acid (published in Poggendorff's *Annalen*, lxxiii., p. 383 and following). The author describes at length, the preparation, properties, and per cental composition of a salt which, in 100 parts, consists of:—Phosphoric acid, 38.32; oxide of copper, 46.45; soda, 8.84; water, 6.75.

Researches on the Isomerism of the Benzol Series.—(Twelfth paper.)—F. Beilstein and A. Kuhlberg. —This paper treats on the isomeric toluidines, and is divided into the following sections:—*Para-toluidine*; *meta-toluidine*; *ortho-toluidine*.

Analysis of Pyrosmalith.—Dr. F. Wöhler. —Pyrosmalith is, according to the author, a rare mineral, only met with in the iron mines of Nordmarken, Sweden. The author quotes the analysis made of this mineral, in 1815, by Dr. Hisinger, and observes that the quantity of chlorine found by that *savant* is probably too low. The analysis now made by the author gives, for the composition of pyrosmalith, the following result, in 100 parts:—Silica, 36.42; protoxide of iron, 22.91; protoxide of manganese, 22.52; peroxide of iron, 5.10; perchloride of iron, 9.73; water, 3.32. The mineral contains, therefore, oxychloride of iron (14.88 per cent = 6.53 per cent chlorine) combined with a double silicate of the protoxides of iron and manganese. Formula—

Presence of Urea in Bile as a Normal Constituent of that Fluid.—O. Popp. —This paper, chiefly of physiological importance, contains the detailed account of the means of separating urea from bile.

Chromate of Chromic Oxide.—O. Popp.

Some of the Products of Conversion of Phenol.—L. Barth. —This lengthy essay contains an account of the author's experiments on testing the action of fusing caustic potassa upon phenol and the various products resulting therefrom.

Bromo-Phenol-Sulpho Acids.—C. Senhofer. —This monograph is divided into the following sections:—The bromine substitution-products of phenol-*para*-sulpho acid; the bromine substitution-products from phenol-*meta*-sulpho acid.

Preliminary Notice on some of the Derivatives Obtainable from Gallic Acid.—O. Rembold. —This notice treats on a body obtained by the author by first causing arsenic acid to act upon gallic acid at 120°, and next acting upon the insoluble body thereby generated with sodium amalgam, which is insoluble in water. The author is engaged with further experiments on this subject.

On Saliretine.—K. Kraut.

Sitzungsberichte der Königlich Bayerischen Akademie der Wissenschaften zu München, vol. lii., No. 2, 1870.

This number contains the following papers and memoirs relating to physico-chemical and collateral sciences:—

Resin contained in the Tampico Jalap.—Dr. Spigatio. —The author says that, in addition to the well-known and officinal jalap-root, the produce of the *Ipomoea purga* of Dr. Wenderoth, there has been imported of late, from Mexico, a new kind of jalap-root, under the name of Tampico jalap, Mr. D. Hanbury* having described this root as the produce of the *Ipomoea simulans*, belonging to the same natural order as the other plants which produce jalap-roots—viz., *Convolvulaceae*. The author instituted a series of experiments with the view of comparing the properties of the resins contained in the Tampico (the name of a seaport town and river of Mexico) and ordinary jalap-roots. The Tampico resin he calls tampicine, and the resin contained in the ordinary jalap-root, convolvuline. Tampicine is obtained by first exhausting the Tampico-root with water, and then dissolving the resin by means of alcohol; after evaporation of that fluid, the residue is purified by boiling with charcoal. Tampicine agrees generally with convolvuline, as regards its properties, but it is distinguished from convolvuline by being soluble in ether, a property also possessed by jalapine (the resin met with in the root of the *Ipomoea orizabensis*), which, however, differs in its elementary composition. The alcoholic and ethereal solutions of tampicine exhibit a weak acid reaction to test-paper. Like convolvuline, tampicine is converted, by the action of bases, into an acid soluble in water, the elements of that liquid being thereby taken up. The author calls this acid tampicinic acid. Tampicine also resembles convolvuline in being a glucoside, which, by the action of dilute acids, is split up into sugar and a kind of fatty acid, tampicollic acid. Tampicine is soluble in acetic acid, and even at boiling heat is not split up into sugar and tampicollic acid; water precipitates the tampicine unaltered from its acetic acid solution. It is far more sensitive for heat than convolvuline, and cannot, without decomposition, be kept, even at 100°, for any length of time. The melting-point of tampicine is 130°; the formula, dried over sulphuric acid in vacuum, is $\text{C}_{21}\text{H}_{32}\text{O}_{12}$; while the formula of convolvuline is, according to Dr. Mayer, $\text{C}_{21}\text{H}_{30}\text{O}_{12}$. Tampicinic acid is an amorphous, yellowish

coloured, brittle mass, void of odour, and exhibiting a sour, bitterish taste; attracts moisture from the air; is readily soluble in water and alcohol, but not in ether; its aqueous solution is a strongly acid fluid which decomposes alkaline carbonates, but that solution is not precipitated by any saline or metallic solutions, excepting those of acetate of lead and bichloride of mercury, which produce a faint turbidity, while a solution of basic acetate of lead causes a bulky, white, flocculent precipitate. Tampicinic acid, heated upon a piece of platinum foil in contact with air, burns, and leaves no residue. The formula of this acid is $\text{C}_{21}\text{H}_{30}\text{O}_{17}$; it is generated from tampicine by the assimilation of $3\text{H}_2\text{O}$. Convolvulinic acid is, according to Dr. Mayer, $\text{C}_{21}\text{H}_{30}\text{O}_{16} + 12\text{H}_2\text{O}$. Tampicollic acid, when pure, is a snow-white coloured crystalline body, void of smell, of an acid taste, readily soluble in alcohol, but less so in ether; it melts, when submitted to heat, forming an oily fluid which produces a similar stain on paper to oil; on cooling, it becomes a hard, white-coloured stearic acid like mass. The alcoholic solution of this acid decomposes alkaline carbonates. The salts this acid forms with alkalis (potassa and soda) are soluble in water; its other combinations with bases are insoluble in that liquid. The formula of tampicinic acid is $\text{C}_{21}\text{H}_{32}\text{O}_{12}$, while the formula of convolvulinic acid is $\text{C}_{21}\text{H}_{34}\text{O}_{12}$. The process of the splitting-up of tampicine can be represented by the following formula:—

The author finally states that, according to his experiments, the medicinal use of tampicine is not to be recommended, its action upon the human organism being less sure, and by no means the same as that of convolvuline.

Researches on the Action of the Electrophor.—W. von Besold. —The contents of this long and exhaustive memoir may be summarised as follows:—The electricity generated by rubbing the upper surface of the resin-plate of the electrophor exerts a diffusing action upon the lower or bottom resin-plate. If the primary excitation is sufficiently strong, the negative electricity of the lower plate forces its way through the layer of air existing between it and the resin-cake, and thereby causes the production of electric sparks. At the same time, the electricity primarily generated becomes partly fixed to the upper plate; and this process lessens the activity of the electricity of the disc, and also prevents electrical action between the two plates. The negative electricity of the disc, called forth by diffusion, remains in the disc, and can be made active by the removal of the disc. The efficiency of the instrument depends greatly upon the fact, that, when the disc is in position, it is in circumstances highly favourable to intense inductive action.

NOTES AND QUERIES.

University of Giessen.—"Vox's" best plan is to go Giessen and follow the legitimate course of studies, and so obtain the degree.

Pyrotechny.—Can any of your readers recommend a thoroughly practical work on pyrotechny in either French or German, if there is not such a one in English? Also, where the apparatus can be had.—ERNEST J. WITHEFORD.

Turkey Red.—I shall take it as a favour if any of your readers would kindly tell me how this new Turkey red, from aurine (rosolic acid), is prepared for the use of paper printers. Aurine is changed by alkalis into a crimson, but I wish to know how this crimson is precipitated.—MAEGENTA.

Alkaline Fluorides.—Reply to O.X.O.)—When hydrofluoric acid is saturated with potassa and evaporated to dryness, a deliquescent and difficultly crystallisable compound is obtained, which can be intensely heated without decomposition; its solution acts upon glass. The salt is decomposed by sulphuric acid and also by chlorine, hydrofluoric acid being evolved.

Crith.—The word "crith," proposed by Dr. Hofmann, was a very convenient one to express the weight of a litre of hydrogen, and has been adopted by some chemists. However, most teachers, I believe, now prefer to use Dr. Williamson's standard volume of 112 litres in making calculations with gases. I have been cudgelling my brain for some time past to find a euphonious word to express this volume. Will you allow me in the columns of your influential journal to draw the attention of our classical friends to this subject, and to ask them for suggestions?—TEACHER.

MEETINGS FOR THE WEEK.

MONDAY, 12th.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action." (Educational Course.)
— Medical, 8.
— Royal Geographical, 8.30.

TUESDAY, 13th.—Institute of Civil Engineers, 8.
— Photographic, 8.
— Ethnological, 8.

WEDNESDAY, 14th.—Society of Arts, 8.
— Microscopical, 8.

THURSDAY, 15th.—London Institution, 7.30. W. Mattieu Williams, F.C.S., "On Count Rumford and his Philosophical Work."
— Royal, 8.30.
— Royal Society Club, 6.
— Chemical, 8. W. H. Perkin, F.R.S., "On some New Derivatives of Coumarin."

THE CHEMICAL NEWS.

VOL. XXII. No. 577.

ON THE SEWAGE QUESTION.*

By EDWARD C. C. STANFORD, F.C.S.

I HAVE been requested by the Committee of the Sanitary Section of the Philosophical Society to remind the Section of the origin of its existence; and, after the great variety of excellent papers read in this Section last year, it is, perhaps, as well to remember that we grew out of the Sewage Association of Glasgow, and that the subject which that Association met to discuss is still, even more than it was then, one of the most important and the most interesting, as it confessedly is also still the most difficult problem of the day.

I have much pleasure in recording our early labours, because they were not without an important result. After a great number of discussions, where every possible variety of opinion was expressed, and where most of us commenced with the usual strong prejudice in favour of sewage by water carriage, we actually did pass *unanimously*, at the close of the session in 1868, the following resolution, first in committee and then in open meeting:—

"That, in the course of the discussions which have taken place at the Association's meetings, sufficient evidence has been produced to warrant them in recommending the authorities, before coming to any conclusion on the subject of the sewage, and purification of the river, to make experiments on the practicability of such schemes as proceed on the principle of providing that fecal matters must no longer be allowed to enter the common sewers or the river."

Again, I find in the minutes of a meeting in this section on the 28th December, 1869, in the discussion on Dr. Grey's paper advocating a system of water carriage, that—"The Section expressed disapproval of that mode, and affirmed to the finding of the Sewage Association on the subject."

I remind the Section of these resolutions because I consider them real marks of progress, and because they show that we have had the courage to pause, and seek other solutions of the difficulty than that one idea constantly thrust upon us by high engineering authorities, which sounds very like the cry of "Water, water everywhere, but not a drop to drink."

The present year has been marked by the appearance of two authoritative reports—the "Report of the Rivers' Pollution Royal Commission," and the Report of the British Association Committee "On the Treatment and Utilisation of Sewage," which has appeared as a volume by Professor W. N. Corfield. Of the Report of the Royal Commission, I feel bound to say that it is the most valuable and comprehensive which has yet appeared; the innumerable analyses of water and sewage testify to the completeness of the inquiry; and show that Dr. Frankland has taken up the subject with his usual accuracy and breadth of view. The nature of the enquiry, that of the pollution of rivers, has, however, naturally led the Royal Commissioners to look at our town refuse at the large, and, therefore, in my opinion, the wrong end, and to try to stem the tide of contagion after it has become a river, rather than to deal with the pollution at its source. Irrigation, then, as a necessary consequence, will probably be duly enforced as the compulsory result of a compulsory water-closet.

Of the Report of the British Association Committee, I cannot, however, speak so favourably. This committee

was appointed in 1868, and a short but valuable statistical report from it was read at Exeter in the following year. It was then re-appointed, with a grant of £50 from the Association, and several new members added. The Committee then took the unprecedented course of applying to cities and towns to contribute to their funds in sums proportioned to the number of inhabitants; they thus raised about £1500, of which I understand about £500 have been expended. Several gentlemen representing towns who had thus subscribed indignantly asked, at Liverpool, what had been done with their money; and Prof. Corfield's book, since published, was their promised solace. The actual report will not appear till the publication of the *Proceedings of the British Association for 1870*, but this work is published under the authority of the Committee, and pretends to be a synopsis of its views. There appears, however, to have been some strong dissension amongst the Committee, for one of their number—in fact, the reporter of the former year—at one of the Liverpool meetings, expressly denied all complicity in the Report of this year. The Committee underwent so severe a handling in two sections where the report was read, that they withdrew it from a third, where it was also to have appeared. My impression certainly is that they would have been more severely handled if Professor Corfield's work had been then published as the principal result of their labours. This work is a *re-chauffée* of the Report of the Royal Commission, in which the facts of the original are not improved on by the *opinions* of the author.

Corporations and town councils who have subscribed to the British Association Committee will, no doubt, be gratified to learn that they can purchase this interesting volume for 7s. 6d., and read in abstract what has been already published in *extenso* in a Government blue-book, well illustrated with plans, maps, and engravings, for 5s. Some who have subscribed largely may not object to a balance-sheet in the next edition.

The Committee were charged at Liverpool with a strong prejudice in favour of water carriage and irrigation; and certainly no one can read this work without seeing at once that its purpose is directly to enunciate these views. One remarkable part of this report, however, is that it advocates the use of a separate system of sewers for house sewage, and of settling or filtering the sewage before employment for irrigation. Now the former is an extraordinary admission for sanitary engineers to make; it shows the correctness of our views, and concedes the real point of our demands. We have always been told that a double set of sewers would entirely upset our existing system, and that it never could be carried out. Amongst others, Dr. Anderson, in his report, states it to be impossible. Having now admitted this necessity, the whole question is reversed, and I maintain that the step is in the right direction; and the next consideration (which ought to have been the first) should be to really carefully examine the best methods of dealing with house refuse. This, I maintain, has never been fully, fairly, and systematically done. In neither of the reports now referred to has sufficient justice been done, or sufficient attention been paid, to any system of removal of excreta, other than by water carriage.

Lieurnur's pneumatic system is not alluded to at all in the Rivers' Pollution Report, and dismissed in a few words without evidence in the other.

The charcoal method of removal, though brought forward at the British Association at Exeter, and before some of the Committee, is alluded to in neither. Nor is the remarkable deterioration of lead pipes, when attached to water-closets, mentioned, although the evidence has never been contradicted. The ingenious method of distillation of sewage proposed by Mr. Chapman is also unnoticed. Mr. Hoey's method of saving water in the ordinary closets is not spoken of. Weare's method of sewage filtration through charcoal and ashes is not referred to. Now these processes may not have come under the notice of the Royal Commission; but I maintain that,

* Read before the Glasgow Philosophical Society (Sanitary Section), Nov. 9th, 1870.

whatever their value, they ought to have been thoroughly examined by the British Association Committee, who define the term "sewage" as applying "to all refuse of human habitations affecting the health of the country."

In a paper read before you two years ago, I reduced the methods of removal to three—so-called water, air, and earth carriage, and, under these, described how each method should be carried out and tested. I wish now briefly to repeat my views, that you may see how far they were right by these two new lights which have since dawned on us. If water carriage be continued, then it should be conducted by a separate system of cast-iron pipes, which could be easily flushed, and in which gases could not accumulate. If air carriage, then Lieurnur's pneumatic system ought to be thoroughly tested. I showed how economically the fecal matter could be forced from the reservoirs, by a small compressing air-pump, out to a chemical work at any distance, where it could be easily dealt with. If the Lieurnur process gives out any odour, this must be modified by the use of a little powdered charcoal, which could be easily applied by Weare's pepper-box dry-closet lid. If earth carriage be preferred, as I think it eventually will be, then I advised its being re-carbonised until it assumes the form of X charcoal—that is, being re-burned until it represents the charcoal obtained from the excreta. As to ordinary sewage, I gave it as my opinion that no process could ever be devised that would extract from it, chemically, its manurial value. No evidence since has shaken that opinion; and all must agree with Dr. Frankland in his sweeping condemnation of the A B C and other processes of this kind, although I remember our Corporation would not believe in any of us when we tried to prove their absurdity. I stated then, too, that intermittent filtration and irrigation were the only means of purifying sewage. These opinions are fully corroborated by the Rivers' Commission Report. I strongly recommended charcoal for this filtration—by preference, seaweed or X charcoal, and exhibited specimens of sewage thus purified, specimens now again before you in actual *statu quo*. The purification is perfect, but I held out no hopes that more than the suspended matters would be retained. I am induced to allude again more particularly to this filtration, because Messrs. Weare's system has since been introduced to the notice of our authorities. Weare's process is a method of filtration through ashes and charcoal; by the kindness of Mr. Johnson, I am enabled to show you some plans of this method. There can be no doubt of the purification effected; of course, the available nitrogen cannot be separated from the sewage, but the patentees appear to separate sufficient manurial value to make the process pay and produce a saleable manure; and, therefore, even to precede irrigation, it would be a valuable adjunct. The specimens you see before you for the second time are those of thick pure sewage from the bottom of the sewage-well at Worthing, and of Glasgow sewage before and after filtration through seaweed charcoal. The Glasgow sewage contains a good deal of iron, and is not now

offensive; but the other is a pure house-sewage—and any one removing the stopper, and inserting his nose, will believe at once that four years' standing, including some months in the Paris Exhibition, has in no way impaired its character as a choice essence of epidemics; nor has it effected the purity of the filtered water.

I append analyses of the sewage before and after treatment—

2. Glasgow, March, 1868; sewer, south side, below Jamaica Bridge.

3. Concentrated Worthing sewage; bottom of well.

4. Concentrated Worthing sewage; after filtration of seaweed charcoal.

The Worthing sewage is a severe test, as it contains four or five times the quantity of solid matter found in ordinary sewage; but the purification is perfect to all appearance. I did not find, however, that the charcoal had retained much of the nitrogen.

The phospho-carbon manure made by Weare and Co. sells at 80s. per ton at the works; and the effluent water from the filters is no doubt efficiently oxidised. The process, as a modified method of charcoal filtration, is well worth a full and searching inquiry.

I think all will agree with me that the water-closet system, if connected with a separate system of pipes, and the sewage subjected to intermittent filtration through charcoal, and then used for irrigation where convenient, or run away when it cannot be so used, would be very much safer than at present. With a modified amount of water something might be done with it; but it is questionable whether even then it would pay for the outlay. Both filtration and irrigation must fail if the storm-waters are still allowed to mix with the sewage, as a sudden storm of rain will upset all the arrangements. The Rivers' Pollution Commissioners, however, appear determined to treat the whole refuse of towns with rainfall in the main sewers; and irrigation is, consequently, with them the only remedy, as such a large quantity of water cannot be filtered. Let us, therefore, in view of their certain recommendation to adopt irrigation for Glasgow, look further into this; and here I borrow a table from Mr. W. R. W. Smith.

Maximum sewage, per day.				
	Gallons.	Tons.		
	57,000,000	254,464	16,000 acres.	84,000 acres.
			25 sq. miles.	125 sq. miles.
Sewage in twenty years, per day.				
	Gallons.	Tons.		
	82,000,000	365,983	23,500 acres.	121,400 acres.
			35 sq. miles.	180 sq. miles.

It is based on Messrs. Bateman and Bazalgette's report, from the experience of Mr. Morton, on the Lodge Farm, at 5400 tons per annum of sewage per acre of grass, and at 1100 tons per annum of sewage per acre of cereals; from which it will be seen that, if cereals are to be largely

cultivated, the Corporation will require in 20 years a small farm of 121,400 acres, or 180 square miles, for cereals, unless they can sell the grass of 35 square miles; either would make a considerable demand on the county of Ayrshire.

We shall await with much interest Dr. Frankland's report of the capability of purification of sewage possessed by the Irvine sand, and also the analyses of the Glasgow sewage. Dr. Anderson's report showed it to possess some remarkable peculiarities, with a general strength two-thirds that of London. Now the difference is due to the increased rainfall; but, as this rainfall has again to be encountered by the sewage *in situ* on the farm, it ought to be double the strength of that of London, to have an equal chance of success, and this even if the temperature were equally warm and the atmosphere equally dry. But it does *not* pay in London, and how can we expect it to do so here.

Some instances are given in the Report of Her Majesty's Commission of Sewage Farms, from which I take the highest return per head per annum; in no case do I find any profits shown. The Lodge Farm experience is said to represent a return of five shillings per head of the population.

In a former paper, I said—"Irrigation, the only method of utilising sewage, puts an amount of money-value on the ground out of all proportion to the return obtained by the ratepayers. There appears no doubt that the farmer will not give one halfpenny per ton for it, delivered free of expense. Where gravitation and open carriers can be employed without pumping, its application is remunerative; but in no case is anything like the full money-value obtained to the ratepayer. The cost of transport, where the chemical value of a product is only one penny per ton, is far the more important item." Mr. Hope, of the Lodge Farm, the most prominent advocate of irrigation, has never disproved these assertions.

Professor Corfield says that the British Association Committee will accept no scheme which does not "make it pay." Now, 5400 tons of sewage at one penny per ton for grass land is equal to a top dressing of £22 10s. per acre, that is, its minimum value. Where is the West of Scotland farmer that would dream of using this manure at its market price?

(To be continued.)

ON THE BEHAVIOUR OF ROSANILINE TOWARDS AGENTS OF SUBSTITUTION WHEN ATTACHED TO ANIMAL FIBRES.

By PHILIP HOLLAND.

To everyone who has dipped a piece of wool or silk in an aniline colour must the question have suggested itself, How comes it to pass that these substances show so marked an attraction for the "tar colours," cotton not presenting any affinity? Is the peculiarity to be ascribed to a chemical or to a physical cause, or to both?

It is worthy of note that all substances capable, without special chemical treatment, of absorbing and retaining permanently an aniline colour, belong to the animal kingdoms and are, for the most part, highly nitrogenous.

Wool, silk, albumen, horn, and feathers are remarkable evidences of this peculiarity, whilst cellulose, flax, and such like, which are non-nitrogenous, are indifferent.

M. Schützenberger in his "Traité des Matières Colorantes," tome i., inclines to the opinion that, so far as regards the attraction of animal fibres for the tar colours, it is to be ascribed to a chemical cause, and that the organic substance acts as a mordant, forming with the colours an insoluble organic lake. Whether this opinion still holds ground or is negatived by the researches of Walter Crum, Hellot, and others, who pleaded in favour of a mechanical theory, I am unable to say.† Reflecting on the subject, however, led me to make some experi-

ments to ascertain whether or not the three equivalents of mobile hydrogen in rosaniline would submit to agents of substitution as easily when that base is attached to a fibre as they do when it is free. An answer in the negative would lend additional support to the chemical theory to some extent.

A clear solution of acetate of rosaniline was prepared, and with it specimens of silk and merino were dyed; they were removed before they became so far saturated with colour as to be incapable of absorbing more, then well washed and dried.

A piece of silk about an inch square was put in a tube, together with 2 c.c. of iodide of ethyl. The closed tube was then heated at 100° C. for about two hours, and opened when cold. The silk, which was quite broken up, was changed in colour to a brown-violet. A little forethought would have prevented this unfortunate climax to the experiment. The iodide was not dry, which accounts for the formation of a little hydriodic acid, and consequent destruction of the tissue. The experiment was repeated with re-distilled and dry iodide diluted with six parts by measure of dry benzol. The mixture was enclosed in a small bulb, which was afterwards broken in the sealed tube.

This device prevented the presence of free iodine caused by decomposition of the vapour of the iodide when closing the tube. The latter was then heated at 110° for one hour. The silk, on removal, was found to be dyed a deep violet, and resisted attempts to tear it.

A larger specimen was prepared in a similar manner, using the iodide still further diluted. The brilliancy of colour is equal, I believe, to that of silk dyed in the usual way, and may be expected to resist washing even better, since iodide of tri-ethyl rosaniline, a somewhat insoluble salt, is, in this experiment, precipitated within the cellular structure of the silk.

My success led me to attempt other substitutions. The next derivative of rosaniline which presented itself was the blue. As, however, the "phenylation" of rosaniline by means of aniline only proceeds at 180° C. or thereabouts, a temperature sufficiently high to destroy silk, the experiment was not made.

Fortunately, I recollected the action of aldehyde on acid solutions of magenta, whereby the red changes to a blue-violet. A high temperature is, in this case, unnecessary, a feature exactly suited to the requirements. A portion of crude aldehyde was put into a flask and acidified with H₂SO₄. A piece of the rose-dyed silk was immersed in the liquid. At the end of a few seconds it changed colour, becoming more and more violet as the fluid was agitated. At the end of half an hour the action was complete; the specimen was then washed to remove acid, and dried. The colour is a reddish-violet, very brilliant by day, but only dull by artificial light. This violet is said to be fugitive. It may, perhaps, be less so when fixed as here described. More easy of execution than the former one, this experiment is a further example of the fact that the replaceable hydrogen in rosaniline is just as mobile when that base is attached to a fibre as it is when the base is at liberty. The last experiment may be expeditiously made as follows. Into a long-necked flask is placed some bichromate of potassium together with more than sufficient water to dissolve it when cold (say, six parts by weight); sulphuric acid is then added equal in weight to the bichromate, and the mixture well cooled under a stream of water; the alcohol (methylated) rather more than the weight of the bichromate is added in small portions, shaking the flask, vigorously under the stream of the while. When all the alcohol is added and the flask ceases to communicate heat to the hand the operation is finished. This solution is rich in aldehyde, the heat generated being insufficient to provoke a more complete oxidation, and is quite fitted to produce on the rose-dyed silk the change above described.

Having proceeded thus far in producing substituted colour on silk, it seemed desirable to attempt the produc-

* See CHEMICAL NEWS, vol. xix., p. 255.

† Persoz, "Traité de l'Impression des Tissus," tome ii., p. 128.

tion of a more complex body than aldehyde violet, viz., the green. Unfortunately, the green is, I believe, only formed under conditions wherein silk would be destroyed. A single experiment however, was made with this view.

M. Lucius patented a process some time ago for the preparation of the green in which he takes advantage of the reducing property of H_2S .

Thinking I might succeed in producing the green by heating the rose-dyed silk with solution of H_2S and excess of aldehyde, the experiment was made. The silk, however, was destroyed; the fluid had a green tinge. I hope to return to this matter.

All the above experiments were made with wool, and gave similar results.

Aniline red on cotton, fixed with albumen, is susceptible of conversion into aldehyde violet. Theoretical considerations would scarcely lead one to expect a successful issue in this instance, but would rather imply that insoluble albumen, locking up the colour in the fibre of the cloth, would present a barrier to some extent impassable to cold aqueous solutions. Such does not appear to be the case.

When rose-dyed silk or wool is dipped in a strong solution of aldehyde the change of colour is instantaneous and partakes more of a blue shade; it is very fast to boiling soap. Such a method of using aldehyde violet may be found advantageous in practice and possibly replace other violets more expensive to manufacture.

Chorley, Lancashire.

ON FERMENTATION.*

By Professor A. W. WILLIAMSON, F.R.S.

(Continued from p. 269).

LECTURE II.

OUR last lecture ended at a point at which we had come to recognise a difficulty, which we did not, to any appreciable extent, succeed in solving. By considering in succession a certain small number of processes in which substances induced chemical changes in others which were in contact with them, we classified them, beginning with some very complex cases—cases in which substances, of formulæ so long that, even if I ventured to give you chemical formulæ at all, I should hesitate to give you their formulæ—took part in the decomposition, and gave rise to products themselves having formulæ of no small complication. From those we passed to the consideration of some bodies less complex in their structure, and undergoing changes very much like those which we at first considered, but having this remarkable peculiarity that, in these somewhat simpler cases, the changes were effected not only by organic bodies comparable to ferments, but also, in certain instances, by simple mineral bodies, such as the acids. In this intermediate class we found that the same effects are produced, sometimes by diastase, or such like bodies, and sometimes by sulphuric acid. Then we came to some still more simple cases of decomposition, produced solely by bodies of such simplicity that we chemists have got a tolerably definite idea of them. I gave two cases which I believe I may say are pretty well understood. The resemblance between the different terms of that long series served, as I think it will be admitted by those who followed the chain of reasoning, as an argument in favour of there being some great resemblance in the process which takes place in these changes in the successive terms of the series; and I propose, before we proceed further in the study of these wonderful decompositions, to analyse somewhat the nature of these changes in the simple cases which we last considered, in order that we may get, if possible, something like a master-key—a very simply-formed piece of iron—which will open a variety of locks. The two cases which I allude to were, first, the formation of ether and water from alcohol by the action of oil of vitriol; and,

secondly, the ordinary process of making oil of vitriol in the so-called lead chambers; and I think it will be admitted, even from the very brief and imperfect statement which I was able to make, that we have evidence of the fact that the active substances do return, after they have been doing one bit of that work, from the point from which they started before doing it. I gave a couple of illustrations of that fact. Sulphuric acid is converted, while making alcohol into ether and water, into a substance called sulpho-vinic acid, which differs from it in a good many properties, and then it comes back again to sulphuric acid. Just so with nitric oxide, in the process of making oil of vitriol; it first takes up oxygen and assumes the form of those red fumes, then hands that oxygen over to the sulphurous acid which is in contact with it, thus coming back again to the state of nitric oxide from which it had started. Hence the term which I have suggested for this process is cyclical, to denote the fact which I consider essential, the leading fact, that it is a cycle, the idea of which implies that the road by which it returns is not the same by which it goes, and I want that idea to be suggested by the word. In the case of etherification, I wish I could lawfully use formulæ on the blackboard, but it would not do, for I am sure that the greater number of my audience will agree with me that it would be a liberty which I ought not to take; but chemists are in the habit of denoting, by the aid of formulæ, particulars which require to be fully explained. I mention that because, excluding that ordinary process, the particulars of my argument must, of course, be omitted, inasmuch as I do not use the language by which alone those particulars can be conveyed. When the sulphuric acid acts upon alcohol, and transforms it, by a succession of these cyclical processes, into ether and water, the general kind of process is this:—A little particle of the acid—because each one acts like the rest, and we had better consider one as a sample of the rest—first takes something from a contiguous particle of alcohol, and then it hands over this something to another particle of alcohol. That which the acid takes in the first instance is called, in our ordinary language, ethyl. It is a group consisting of carbon and hydrogen, very much like hydrogen gas—it is a group of those elements, and behaves in a manner closely analogous to hydrogen itself. The acid, in doing that particular work which we have to consider, first takes a particle of this ethyl from one particle of alcohol, and whilst it does so, it gives to the alcohol something in exchange; that something is hydrogen. And by doing this, the sulphuric acid which has taken up this ethyl is converted into sulpho-vinic acid; it has gone half round the circle, in fact. The remainder of its journey consists in reversing, in another way, with another particle of alcohol, that very same kind of interchange which it had undergone in the first instance, that is, it gives up again this little portion of ethyl which it had taken, and resumes hydrogen in place of it. Just as that is the general process when sulphuric acid acts upon alcohol, forming it into ether and water, so in the other process, which I just now reminded you of, there is a similar action, only there is this difference—of course, I speak within those narrow limitations which are imposed upon us by our very imperfect knowledge of even these best-known processes—but, as far as we know, the nitric oxide merely takes up oxygen, but gives up nothing in exchange. Those red fumes which you saw were really nitric oxide *plus* oxygen, not nitric oxide in which oxygen had replaced something else, and that was a difference between the process in that case, and in the one to which I just now referred. Then, again, it simply gives up that oxygen to the particle of sulphurous acid.

The illustrious Liebig, to whom we owe, in this order of phenomena as in every other order which he has touched, some of the most valuable ideas which have guided our researches, suggested many years ago, for the explanation of the phenomena of fermentation, a theory which certainly has rendered very great service, and not the less so from the fact that it has been replaced

* The Cantor Lectures. Delivered before the Society of Arts.

by one more perfect. In building a house, it is certainly no proof that a scaffolding is unnecessary that in the final structure the scaffolding is not maintained; and so in the progress of our science, as in every other science, each part of the work must be judged from its usefulness in aiding the carrying on of the building, even though the particular substance which was placed there at the time does not finally form part of the structure itself. Liebig's explanation really is classic, and well worthy of a few minutes' consideration. He classed together a considerable number of cases of chemical action which bore, at least upon their surface, a considerable resemblance to one another, and he saw in them something in common, and by this one resemblance which they had he classed them, considering it to be their essential characteristic feature. For example, there is a substance which is made, by a process of oxidation of a compound something like lime. It is called baric peroxide. Thenard had found that the oxygen which is here taken up by the baryta can, by a particular process, be passed over to water, so that, in fact, Thenard, from his oxide of baryta, made by a process which I will repeat on a small scale, some oxidised water or peroxide of hydrogen, as it is commonly called. Here is some of the peroxide suspended in water, and by adding an acid hydrogen salt, the hydric nitrate, in small quantities (for if I add it in too large quantities, I should destroy the peroxide, which is a very tender substance, and requires to be treated tenderly), I should gradually transfer the oxygen from the baryta, with which it was at first combined, to the water which is here present. This oxidised water, or peroxide of hydrogen, gives up this oxygen which it has just taken up very easily indeed—in fact, the difficulty is to prevent it doing so. Amongst processes of that kind, I will show you one simple one. I will pour into the water in this large beaker glass some of the solution which I have just prepared, and then add to it a few drops of this red liquid, which is a solution containing chromic acid combined with potash. You see, no doubt, that although I have only added half-a-dozen drops, there is evidence of a chemical change, and the deep blue colour which is formed by the contact of the two liquids is due to the formation of a new compound. The chromic acid, which has a red colour, takes up oxygen from that peroxide of hydrogen, forming a blue compound. I have purposely chosen this particular instance, because the process is a slow one, and we have time to see its intermediate changes. I will leave the glass here, and in a few minutes you will see the blue colour will have disappeared, and in place of it we shall have a dirty green colour, hardly visible. Whilst that change takes place, if we were to take means to examine carefully what was going on, we should find that oxygen gas passed off, and if we examined the green substance present at the end of the process, and compared it to this original red chromic acid, we should find that it consists of chromic acid *minus* oxygen. The peroxide takes away oxygen from this chromic acid, and yet the chromic acid has got hold of its oxygen pretty firmly; it requires a considerable amount of energy to tear away even that part which is torn away by the process. But at the same time the oxygenated water is losing part of its oxygen. The deoxidation of the peroxide induces the chromic acid to give up some of its oxygen; the one body induces in the other a change similar to that which itself is undergoing. The peroxide of hydrogen is losing oxygen, and it makes the chromic acid also lose oxygen. To state the process in general terms, I may well use the expression of Liebig, and call it contagious action. There are many other cases of similar processes. Here is a bit of rotten wood; if I were to moisten it and put it into a convenient flask, leaving room for a quantity of air, closing the mouth of the flask with a good cork, and leaving it for a day or two, also putting with the air a little hydrogen gas, which, you know probably, is capable of combining with oxygen, I should, on examining the mixture of air and hydrogen after it had been in contact some time with this rotten

wood, find that the hydrogen had been removed from the air, and at the same time the oxygen of the air which had been mixed with it had disappeared. Now, this wood is actually undergoing a process of combustion—it is actually absorbing oxygen, or being burnt, very slowly indeed, but still at a rate which is not unimportant, if you want it to last for any length of time. De Saussure, who noticed this, attributed the oxidation of the hydrogen gas to the fact that the wood is itself undergoing oxidation. I will take another case of the same kind. I will put into a little flask some of that peroxide of hydrogen, and will show you another decomposition of it, which is rather more convenient in one respect than the one I first took, as it will show us something more of the process. Into this little flask I put some of the same oxidised baryta which I used just now, and I will fit up the flask in such a manner that the gas, which will come off in a tolerably large quantity, can be collected for examination. I will then put in contact with it a substance called silver oxide, first driving out of the flask all the air which it at present contains. Having driven out the air, I put in a few drops of the nitrate which I employed in the first instance, and then I will put in a solution of silver oxide, which is, in some respects, a good deal like this chromic acid, at all events in one important respect, for it has oxygen, which it can give up under sufficiently strong pressure. You now see there is a great deal of effervescence going on, and the gas which is coming off from the little flask is rising into this jar, where we shall very easily be able to ascertain whether it is oxygen by the ordinary test. I should have been glad, if it had been convenient to do so, to give you one other instance in which a remarkable fact was discovered by Professor Brodie, viz., a case of an action of this kind, where the oxygen taken from the peroxide is in quantity exactly equal to the quantity of oxygen from the other body. Whilst that gas is collected, I must enter shortly upon a theoretical question, apologising for doing so, not that I am ashamed of it, for it is one of the most important theories we possess, but on account of the brevity with which I am compelled to treat it. Oxygen, in the free state, is admitted by chemists to consist of two little atoms linked together. In each of the compounds which I used there was one little atom of the kind. One atom leaves each of them, and when I get free oxygen, I affirm that there has been a process of combination, that the oxygen from the one substance actually combined chemically with the oxygen from the other. This is a theoretical result which has been, in great part, established by Sir Benjamin Brodie, with the help of materials from various sources. What I mentioned in the other case holds good equally in regard to chromic acid and the other cases in which there was apparently no definite proportion of the kind. There is an actual chemical combination between the oxygen of one substance and that of the other; it is not merely that the one substance is compelled to decompose because the other is decomposing; there is between the one substance and the other an interchange, so that a constituent from each one combines with a constituent from the other. To do justice to the importance of this fact I should need to describe a great number of chemical reactions, which at present would be impracticable, but you may take my word for it, that the kind of process which I have described is now known to be one of the commonest in chemistry. The other day, when I mixed two of the commonest substances, there were interchanges between the constituents by a process perfectly analogous to that which takes place here. Here it happens, by an exceptional circumstance, that the element which from the one body combines with the element of the other is of a like kind, whereas, as a rule, you find that unlike elements unite together in these processes. Thus it is that the anomaly which Liebig noticed ceases to be an anomaly, and is brought back to a case of common regular chemical action by the aid of that theory to which I have just alluded.

(To be continued).

SCIENTIFIC NOTES FROM AMERICA.

By PROFESSOR LEEDS.

THE chemists engaged in the manufacture of phosphates for agricultural purposes will be interested in the extensive use which is being made at the present time of large beds of phosphatic material located upon the Ashley River in South Carolina. It occurs in the form of nodules or pebbles, which are enclosed in a layer of bluish mud, the whole having an average thickness of fifteen inches, and extending in a nearly horizontal layer over an area of many square miles. Although it has long been known, and its very abundant fossils were referred by the geologists of the State Survey to the post-pliocene formation, yet the gravest mistake was made by the farmers of the neighbourhood regarding the chemical nature of these phosphatic nodules. They were regarded as siliceous limestones, and the numerous failures which attended the employment of the product arising from burning them in kilns were attributed to the supposed excess of silex contained in them. The pebbles constitute about 63 per cent of the bed, and the yield of phosphatic material to the acre is about 1200 tons.

The first bar of tin ever made in the United States was recently presented to the Society of Pioneers in California. It contains, by assay, 97·09 per cent metallic tin. On one side is engraved the inscription—"First bar of tin ever produced in the United States from the native ore, taken from the San Jacinto Tin Mine, San Bernado County, California. Presented to the Society of California Engineers, by O. P. Sutton, April, 1870."

A trial was recently made of the so-called United States Chemical Fire Engine, upon a vacant lot situated in the suburbs of New York. Two two-storied buildings were erected and filled with tar barrels. Both of them were drenched with gasoline, in order that the flames might rage with great fury. One of the buildings, on ignition, was played upon with a solution of sodic sulphite in numerous small streams, the other with ordinary water. The trial was not satisfactory, because the framework of the buildings was so slight, that both buildings gave way shortly after the fire commenced, and were converted into a heap of ruins. It is claimed by the inventors of these fire engines, that the sodic sulphite is decomposed in contact with burning surfaces, and that the sulphurous acid gas which is disengaged, while efficacious in extinguishing of flames, is less injurious to the firemen than the carbonic acid gas employed in a rival invention.

A great blow has recently been given to the long cherished hopes of many of our chemists and naturalists. It was proposed that four small public parks, known as the Penn Squares, which are located at the intersection of Broad and Market Streets, the two principal thoroughfares of Philadelphia, should be given to the Academy of Natural Sciences, the American Philosophical Society, the Franklin Institute, and the Academy of Fine Arts. All of these institutions have suffered greatly of late years for want of room and suitable accommodations for their collections of specimens, books, models, and painting. But the people in a general election—an impression having been made that public property to a large amount was about to be given away to private parties for private ends—decided by an overwhelming majority in the negative.

At a recent meeting of the American Philosophical Society it was stated by Dr. Genth that, according to Del Rio, an alloy of gold and rhodium is found in Mexico, which contains from 34 to 43 per cent of the latter metal. This discovery has never been confirmed, and there is perhaps no mineralogist living who has ever seen it. Some experiments which he has lately made with residues from San Domingo gold leave very little doubt as to the existence of this very interesting substance. Professor Gabb sent a lot of gold from San Domingo to Dr. Horn, who dissolved out the gold by *aqua regia*, and placed the remainder in Dr. Genth's hands for examina-

tion. He found that it consisted of iridosmine, of a dull yellowish substance in microscopic rounded and angular grains, and a silicate which, under the microscope, appeared to be topaz. One of the yellowish grains acquired metallic lustre when flattened out in an agate mortar. It was almost insoluble in *aqua regia*, but by treating it for several days with a large excess of this solvent, it was finally brought into solution. A trace of ammoniac chloride was added, and the whole evaporated to dryness and sufficiently heated to reduce the gold. Mixed with this were microscopic reddish crystals, which were dissolved in boiling water, filtered, the filtrate evaporated to dryness, and the residue slightly heated, by which it assumed a reddish brown colour. On being fused with potassic bisulphate it gave a slightly rose-coloured mass, soluble in water, and precipitated yellow by ammonia. From these reactions there seems to be no doubt that the yellowish grains are rhodium.

At a subsequent meeting, Dr. Genth exhibited photographs of a new meteoric iron, weighing about twenty pounds, which was found on a small mount in Rockingham Co., N. Carolina. The iron is coated with a crust of hydrated sesquioxide of iron. A polished portion of it, after etching with dilute nitric acid, developed the Widmannstædtian figures, and showed a very remarkable structure of the iron. It is composed of three different kinds of iron—one portion of it is quite homogeneous, and has a very fine granular structure; if, however, the light is reflected in different directions it shows a peculiar glistening, and, very faintly, lines intersecting at angles of about 60° and 120°; this same iron runs into bands of not over 0·5 m.m. diameter, which, at another portion of the iron, intersect at angles of about 60°. The space between the bands is filled with an iron presenting a reticulated structure. Disseminated through the iron are crystals of rhabdite, but few only show a regular arrangement. A preliminary analysis gave—

	Per cent.	
Iron	90·41	
Nickel (cobalt)	8·74	
Copper	0·11	
Iron	0·27	} Phosphide insoluble in chlorhydric acid.
Nickel (cobalt)	0·33	
Phosphorus	0·14	
Traces of a quartz mineral.		

Dr. Genth also exhibited specimens of native iron and native lead from the bed-rock of gold-placers, at Camp Creek, Montana Territory.

The native iron is found in small angular fragments, but slightly coated with rust; the largest which he has seen is about 0·5 inch in length. Etching with dilute nitric acid does not develop any Widmannstædtian figures, but a finely granular structure. Nickel and cobalt are not present. Associated with the iron is native lead, in irregularly shaped rounded and flattened pieces, from the size of a pin's head to about 0·5 inch in diameter.

Philadelphia, Nov. 2, 1870.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 29th, 1870.

R. ANGUS SMITH, Ph.D., F.R.S., Vice-President, in the Chair.

"The Tails of Comets, the Solar Corona, and the Aurora considered as Electric Phenomena," by Professor OSBORNE REYNOLDS, M.A.

Although the tails of comets are usually assumed to be material appendages which accompany these bodies in their flight through the heavens—and the appearance they present certainly warrants such an assumption—yet this is not the only way in which these tails may be accounted for. They may be simply an effect produced by the comet on the material through which it is passing; an effect analogous to that which we sometimes see produced by a very small insect on the surface of still water. We see a dark spot, and on looking closer we find a small fly or moth flapping its wings and creating a disturbance which was visible before the insect which produces it.

There is nothing else that we can conceive their tails to be, so that they must be one or other of these two things; either—

(1) Material appendages of the nucleus, whether the material be limited to the illuminated tail or surround the comet on all sides.

(2) Matter which exists independently of the comet, and on which the comet exerts such a physical influence as to render it visible.

Respecting the composition of these bodies, Sir John Herschel says:—"There is, beyond question, some profound secret and mystery of nature concerned in the phenomenon of their tails. Perhaps it is not too much to hope that future observation, borrowing every aid from rational speculation, grounded on the progress of physical science generally (especially those branches of it which relate to the ætherial or imponderable elements) may ere long enable us to penetrate this mystery, and to declare, whether it is matter in the ordinary acceptation of the term that is projected from their heads with such extravagant velocities, and if not impelled at least directed in its course by reference to the sun as a point of avoidance. In no respect is the question as to the materiality of the tail more forcibly pressed on us for consideration than in that of the enormous sweep which it makes round the sun in perihelio, in the manner of a straight and rigid rod, in defiance of the law of gravitation, nay, even of the received laws of motion, extending (as we have seen in the comets of 1680 and 1843) from near the sun's surface to the earth's orbit, yet whirled round unbroken; in the latter case through an angle of 180° in a little more than two hours. It seems utterly incredible that in such a case it is one and the same material object which is thus brandished. If there could be conceived such a thing as a *negative shadow*, a momentary impression made upon the luminiferous æther behind the comet, this would represent in some degree the conception such a phenomenon irresistibly calls up. But this is not all. Even such an extraordinary excitement of the æther, conceive it as we will, will afford no account of the projection of lateral streamers, of the effusion of light from the nucleus of the comet towards the sun; and its subsequent rejection of the irregular and capricious mode in which that effusion has been seen to take place, none of the clear indications of alternate evaporation and condensation going on in the immense regions of space occupied by the tail and coma—none, in short, of innumerable other facts which link themselves with almost equally irresistible cogency to our ordinary notions of matter and force."

There can be no doubt that if these tails are matter moving with the comet, this matter must be endowed with properties such as we not only have no experience of, but of which we can form no conception. This alone would seem a sufficient reason for rejecting the first hypothesis. Moreover, on the second hypothesis there is no difficulty in the immense velocity with which these tails are projected from the head or whirled round when the comet is in perihelio. For to take the "negative shadow" as an illustration, here we should have a velocity of projection equal to that of light, and the only effect of the whirling would be a slight lagging in the extremity of the tail, causing curvature similar to that which actually exists. And whatever the action may be, if its velocity of emission or transmission be sufficiently great, this effect will be the

same; but whether this hypothesis is to be rejected because involving assumptions beyond conception or contrary to experience, must depend on the answers to the following question—Do we know, or can we conceive, any physical state into which any substance which can be conceived to occupy the space traversed by comets could possibly be brought so as to make it present the appearance exhibited by comets?

Now, I think the answer must be in the affirmative, and that we may leave out the terms conceive and conceivable. For electricity is a well-known state, and gases are well known substances; and when electricity, under certain conditions, as in Dr. Geissler's tubes, is made to traverse exceedingly rare gas, the appearance produced is similar to that of the comets' tails; the rarer this gas is, the more susceptible is it of such a state, and, so far as we know, there is no limit to the extent of gas that may be so illuminated. Hence we may suppose the exciting cause to be electricity, and the material on which it acts and which fills space to have the same properties as those possessed by gas. What is more, we can conceive the sun to be in such a condition as to produce that influence on this electricity which should cause the tail to occupy the direction it does. For such an electric discharge will be powerfully repelled by any body charged with similar electricity in its neighbourhood.

The electricity would be discharged by the comets on account of some influence which the sun may have on them, such an influence being well within the limits of our conception.

The appearances of the comet in detail, such as the emission of jets of light towards the sun and the form of the illuminated envelope, are all such as would necessarily accompany such an electrical discharge.

In fact, if the possibility of such a discharge is admitted, I believe it will explain all the phenomena of comets. As to the possibility, or even the probability, of such a discharge, I think it may be established on very good grounds.

The tails of comets may or may not be one with their heads; but whichever is the case, it is certain that the difference in the appearance of comets and of planets indicates some essential difference either in the materials of which these bodies are respectively composed, or else in the conditions under which their materials exist. Now from the motion of comets we know that their heads follow the same laws of motion and gravitation as all other matter, and therefore we have good evidence, so far as it goes, that comets and planets are similarly constituted as regards materials. And since the appearance of a comet changes very much as it passes round the sun, any assumptions with regard to the material of comets in order to account for their difference from planets would not account for the variety of appearance the same comet presents at different times. On the other hand, the conditions of comets and planets must necessarily be very different, from the extreme difference in the shapes of the orbits they describe. Each planet remains nearly at a constant distance from the sun (whatever that distance may be), so that the heat or any physical effect the sun may have upon it will also be constant; on the comets its action must change rapidly from time to time, particularly when the comet is in certain parts of its orbit. Hence we may say that the temperature and general physical condition of planets is nearly constant, and that of comets for the most part continually varying.

There is, too, a very remarkable connection between the appearance of the comet and the rate at which the sun's action on it changes. Herschel says:—"Sometimes they first make their appearance as faint and slow moving objects, with little or no tail, but by degrees accelerate, enlarge, and throw out from them this appendage, which increases in length and brightness till (as always happens in such cases) they approach the sun and are lost in his beams. After a time they again emerge on the other side, receding from the sun with a

velocity at first rapid, but gradually decaying. It is, for the most part, after thus passing the sun that they shine forth in all their splendour, and their tails acquire their greatest length and development; thus indicating plainly the sun's rays as the exciting cause of that extraordinary emanation. As they continue to recede from the sun their motion diminishes and their tail dies away, or is absorbed into the head, which itself grows continually feebler, and is at length altogether lost sight of."

Here, although unconsciously, Herschel has connected the increase of brightness with the increase of speed with which comets approach the sun, and the diminution in brightness, with the diminution of the velocity with which they leave the sun. And although from Herschel's remark just quoted it might be inferred that proximity to the sun is the cause of the increase of brightness, this is proved not to be the case, for (as in the case of Halley's comet) when near its perihelion the tail always dies away, and the comet shrinks. Thus when the comet is nearest to the sun there is no development of tail, which shows clearly that it is not the intensity of the sun's rays but the change in their intensity that is the exciting cause of these extraordinary appearances. So that there is no reason to suppose that a planet composed of the same material as a comet, no matter how close to the sun, would show a vestige of tail or other cometic appearance.

It is, then, to this change in position that we must attribute those peculiar appearances which belong to comets.

Now, is not electricity the very effect which would naturally result from such a state of change and variation in condition?

A. De la Rive remarks, "Electricity is one of the most frequent forms which the forces of nature assume in their transformations. It certainly often accompanies a change in temperature. There is every indication that it is so in our atmosphere, for the times when its intensity is a maximum are just after sunrise and just after sunset, both winter and summer."

From these reasons it seems to me not only possible but probable that these strange visitors to our system are clothed in electrical garments with which the regular inhabitants are unacquainted.

The electricity must, after all, depend on the composition of the comet, for known substances do not all show the same electrical properties. Hence, by assuming comets to be composed of various materials, we have a source to attribute the different appearances presented by the different individuals. To the same source we may attribute the irregularity in the direction of their tails and the lateral streamers they occasionally send out.

Secondly, I think this electrical hypothesis is supported by the, to me, seeming analogy between comets, the corona, and the aurora; an analogy which suggests that they must all be due to the same cause. They may be all described as streams of light, or streamers, having their starting point more or less undefined, and traversing spaces of such extent and with such velocities as entirely to preclude the possibility of their being material in any sense of that word with which we are acquainted.

The aurora has long been considered as an electric phenomenon, and recently the same effect has been produced by the discharge of electricity of very great intensity through a very rare gas, there being no limit to the space which it will thus traverse. This being so, why should not the tails of comets and the corona also be electric phenomena? Their appearance and behaviour correspond exactly with those of the aurora, and there is surely nothing very difficult in imagining the sun which is the source of so much heat being also the source of some electricity. Neither will there appear anything wonderful in the electricity of comets when we consider that of the earth. We must not look on our inability to explain the cause of such an electric discharge as fatal to its existence, for we cannot any more explain the existence of the electricity which causes the aurora. If we cannot explain

from whence these electricities come, we can at least show that the conditions which are most favourable to the development of the aurora exist in much greater force on the comets than they do on the earth. The greatest development of the aurora borealis takes place at the equinoxes. There is a cessation in summer, and another in winter. Now, the equinoxes are the times when the action of the sun on our northern hemisphere is changing most rapidly. Hence the condition favourable for the aurora is changed in the action of the sun. The same thing is pointed out by the diurnal variation in the electricity of the atmosphere. Now, as has been already shown, the change in temperature on the comets is incomparably greater than it is on the earth, and its variation corresponds with the variation in the splendour of the comet.

Angström has also shown that the light from the aurora, the corona, and the zodiacal light, are all of the same character, or all give the same bright lines when viewed through the spectroscopic, and that these lines correspond to the light from no known substance. This indicates that whatever this light may be, the incandescent material is the same in all cases; or may we not assume that it is the medium which fills space that is illuminated by the electric discharges? This would be supported by the fact that the light from the heads of two small comets indicated carbon, whereas that from the tails only gave a faint continuous spectrum. For an electric discharge would first illuminate the atmosphere of the comet, or even carry some of the solid material off in a state of vapour, and then pass off to the surrounding medium. Thus, while the spectrum from the head would be that of cometary matter, the tail would be due to the incandescent ether.

I would here suggest that gas, when rendered incandescent by electricity, may reflect light—it will certainly cast a shadow from the electric light—and if this be the case, part of the light from comets' tails may after all be reflected sunlight.

At any rate, it is certain that the appearance of streamers, the rapidity of change and emission, the perfect transparency and the wave-like fluctuations which belong to these phenomena, are all exhibited by the electric brush; in fact, the electric brush will explain all the appearances, which have defied all attempts at explanation on a material hypothesis.

I have only to add that the main assumption involved in the electric theory is, that space is occupied by matter having similar electrical properties to those of these; and I would ask, is it not more rational to make such an assumption than it is to attribute unknown and inconceivable properties to cometary matter?

Theories even, if founded only on rational speculation, often, I believe, prove very useful, inasmuch as they afford observers a definite purpose in their observations—something to look for, something to establish or to refute; and I publish these speculations of mine at this particular moment in the hope that they may perchance serve such a purpose.

"On Iso-di-naphthyl," by WATSON SMITH, F.C.S. Communicated by Professor Roscoe, F.R.S.

About the commencement of the month of March, 1870, when endeavouring, on the suggestion of Mr. John Barrow, in whose laboratory I was then engaged, to obtain anthracene by the action of a red heat upon naphthalene, the vapour of this body being passed through a red-hot tube, I found that, instead of the anticipated result occurring, according to the equation—

a body was obtained which had a melting-point and also a boiling-point pretty nearly agreeing with those of anthracene, but almost all its other properties were dissimilar to those characterising that body.

This substance I found to fuse at from 200° to 204° C., its boiling-point lying over that of mercury considerably, and also over that of anthracene as nearly as I could judge. It is difficultly soluble in alcohol and ether, more

soluble in carbon tetrachloride and benzol, freely soluble, even in the cold, in carbonic disulphide and oil of turpentine.

From all the above solutions except that of the turpentine it crystallises in beautiful silky rhomboidal plates, which, on drying, interlaminate, and possess a delicate light yellowish green colour and silky lustre. From the turpentine it crystallises in beautiful white lance-shaped crystals congregating in tufts. Its subliming-point lies considerably below its boiling-point, indeed not far above its melting-point.

It may be obtained perfectly white by carefully subliming the re-crystallised substance at as low a temperature as possible. If the semi-purified body be re-crystallised from any of the above-named solvents, the mother liquors on filtering are found to have acquired a beautiful blue fluorescence, but the perfectly pure substance no longer yields a fluorescent solution.

A mixture of two parts of potassium bichromate and sulphuric acid, cause energetic oxidation of this substance, but no colouring matter is obtained by treating the product of oxidation so obtained, by Perkin's method for obtaining alizarin from anthracinon.

Cold sulphuric acid is without action upon it. Warm sulphuric acid dissolves it, if pure, with a slight purplish colour. If containing any of the yellow substance which always contaminates the crude body, the warm acid assumes a blue colour, which, on further warming, becomes green and then brown.

Nitric acid oxidises it, with liberation of nitrous fumes.

Chlorine passed over it in the cold does not affect it, and apparently not even on slightly warming.

I find that it is impossible to distil naphthalin to dryness in any quantity, without this body being formed in minute quantity. If an appreciable quantity be not obtained on first distillation, it will be by transferring back the distillate to the retort and again distilling to dryness; a minute quantity of high boiling residue will then be obtained, raising the temperature towards 300° C.

A quantity of the pure substance, submitted to organic analysis, furnished the following numbers:—

		Grms.	
I.	0.1240 gm. of substance gave	0.4307 CO ₂	
		and 0.0624 H ₂ O.	
II.	0.1237 " " "	0.4284 CO ₂	
		0.0626 H ₂ O.	
		Calculated for	
		I.	II.
			C ₁₀ H ₇
			C ₁₀ H ₇
Carbon	94.72	94.46	94.49
Hydrogen	5.59	5.62	5.51
	100.31	100.08	100.00

The hydrogen evolved in the process was collected and measured, and the following calculation made:—

Weight of naphthalin converted 26.30 grms. (nearly).
Volume of hydrogen at 0° C. . . . = 2359.7 c.c.
= 0.2107 gm. H.

$$\frac{256}{2C_{10}H_8} = \frac{C_{10}H_7}{C_{10}H_7} \cdot \frac{2}{1} \therefore 26.3 \text{ grms. lose } 0.2055 \text{ gm. H.}$$

Hydrogen actually liberated = 0.2107 gm.
Hydrogen calculated as above = 0.2055 gm.

For the formula $7C_{10}H_8 = 5C_{14}H_{10} + 6H = 0.1861 \text{ gm. of H. must be liberated.}$

From these considerations, and seeing that the properties of the body considerably differ from those of di-naphthyl as obtained by Dr. F. Lossen,* I propose to regard this body as an isomer, and propose to name it accordingly Iso-di-naphthyl.

NOTICES OF BOOKS.

A Cyclopedia of Quantitative Chemical Analysis. By FRANK H. STORER, A.M., Professor of General and Analytical Chemistry in the Massachusetts Institute of Technology. Part I. Boston and Cambridge (U.S.): Sever, Francis, and Co. London: E. and F. N. Spon. 1870.

THIS work will be welcomed by all who take an interest in chemistry as a step in the right direction. In compiling the book, the object of the author (well-known to the scientific public as an accomplished *savant* and an excellent editor of several valuable works) has been not only to provide the student and working chemist with a comprehensive dictionary of quantitative processes, but to call the attention of the chemical fraternity to the question of the possibility of presenting this branch of chemistry in a more serviceable and manageable form than has been customary hitherto. The work, indeed, in its first edition is to be considered as an experiment only. The substances are classified in alphabetical order, and every process is referred to the fundamental fact or principle upon which it depends. As instances of the method adopted by the author we give the following extracts:—

ACETIC ACID.—*Principle I.* Power of neutralising alkaline solutions. *Applications:* Estimation of free acetic acid in vinegar, pyroligneous acid, and other aqueous solutions (Method A); Determination of acetic acid in certain acetates from which caustic soda precipitates insoluble hydrates or oxides (Method B). *Method A.*—A weighed or measured quantity (10 grms. of vinegar will be enough in most cases) of the solution to be examined is reddened slightly with litmus, and then treated with test-alkali until the whole of the acid is neutralised, and the colour of the litmus changed to blue (see Acidimetry).

ANTIMONY [Compare antimony compounds.]—Antimony is estimated as metallic antimony, as sulphide of antimony, antimoniate of antimony, antimoniate of sodium, or by titration, as has been explained under antimonious acid. *Principle I.* Sparring solubility of the metal in chlorhydric acid.

CANTHARIDIN.—*Principle.* Sparring solubility in bisulphide of carbon and in alcohol.

CARBONATE OF LEAD.—*Principle I.* Insolubility in cold water. *Applications:* Estimation of lead in all salts of that metal which are soluble in water, or from which the lead can be dissolved by nitric acid; separation of Pb. from Mn.

These few instances may give the reader some idea, though a very inadequate one, of the mode of treatment of the matter and arrangement of the subject. It would be impossible to enter into minute details of this work, which indeed, when completed, will be for analytical chemistry what Watts's "Dictionary" is for chemistry in general. It is not only important that the analyst should have a dictionary of all known methods from which to choose the one which seems best to fulfil the conditions and requirements of any new problem which may come before him, but there will always be needed books or tables devoted to illustrations of the various kinds of analyses which are likely to occur in practice. But if we were once in possession of a general encyclopædia covering the entire field of analysis, it would be easy to draw up long lists of these special schemes in a very few words. For example: A residual product from some of the chemical works at Stassfurt, in Germany, sent into commerce to be sold as a fertiliser, contains the sulphates of potassium, magnesium, and calcium; the chlorides of potassium, sodium, and magnesium, and a quantity of oxide of iron, magnesia, and sand, insoluble in water. But the commercial value of any given sample of the substance depends upon the proportion of potassium which is contained in it. Several methods

* *Ann der Chemie und Pharm.*, Band cxliv. 71, 1867.

have been employed for estimating the potassium. After the matters insoluble in water have been got rid of by filtration, they might be briefly described as follows: (a.) Remove the SO_3 with BaCl_2 , as sulphate of barium, the Mg with BaO , H_2O , as hydrate of magnesium, the Ca and excess of Ba with $(\text{NH}_4)_2\text{O}$, CO_2 as carbonate of barium, and estimate the K as chloride and chloroplatinate of potassium. (b.) Remove SO_3 by means of BaCl_2 as sulphate of barium, decompose the chloride of magnesium with oxalic acid, and separate Mg as oxide of magnesium; determine K as chloroplatinate of potassium. (c.) Remove the SO_3 with BaCl_2 as sulphate of barium; the Ba, Ca, and Mg with Na_2CO_3 as carbonate of barium, &c., acidulate the filtrate with HCl , and estimate K in the filtrate as chloride and chloroplatinate of potassium. (d.) Remove the SO_3 with BaCl_2 as sulphate of barium, and estimate K in the filtrate as chloroplatinate of potassium (Stohmann's process). The author of any such tables would of course give reasons why and when either one of the processes would be preferred to the others. In the appendix to the work now under notice, the author intends to give a few examples of this kind of analysis for students' practice.

The names of rare elements have been omitted from this edition simply for want of time to deal with them; and in order that the size and cost of the book might be kept within reasonable bounds it has been thought best to exclude from it all figures of apparatus, but the description of unusual forms of apparatus has been given in minute detail, so that any reader may, if he chooses, by reading the text attentively, make from the description a rough figure for his own use.

Professor Storer's work cannot fail to be a great boon to all chemists, and for compiling it we feel greatly indebted to the talented author. We trust that both the author and publishers will find their labours duly appreciated.

Chemical Problems. By Professor T. E. THORPE, Ph.D., Manchester: J. Galt and Co.

We are glad to welcome this little book. It is introduced by a short preface from the pen of Dr. Roscoe, who says that he feels sure "that by no method can accuracy in a knowledge of chemistry be more surely secured than by attention to the working of well-selected problems,"—and we are quite sure that Professor Roscoe is right. We believe that Dr. Roscoe was one of the first to recognise the value of such questions, and many of our best teachers, whose papers formerly contained questions requiring merely descriptive answers, now largely employ them, and it is certain that a candidate at the examinations of the Science and Art Department, or the examinations of the University of London, cannot hope to succeed unless he possess some facility in chemical calculations.

Dr. Thorpe's little book contains 220 questions. They are well selected, and cover a considerable range, and in the case of those presenting any difficulty, explanations are given.

Most of the questions are new, but some few are taken from the examination papers of the Science and Art Department.

We notice an error in the formula for the calculation of the *calorific intensity* of hydrogen burning in oxygen, which is given thus:—

$$\frac{34462 - (536 \times 9)}{9 \times 0.475} = 6932.8.$$

Since the initial temperature of the gases is supposed to be 0°C .—the latent heat of steam at 0°C . must be employed and not that at 100°C ., so that the formula should be—

$$\frac{34462 - (606.5 \times 9)}{9 \times 0.475} = 6784.3.$$

We notice one other error—a misprint—on page 3. Area of a circle = diameter squared $\times 0.785398$ should be = diameter squared $\times 0.785398$.

The value of the book is increased by an appendix giving a table of four figure logarithms and anti-logarithms, a table of atomic weights, and other tables of constant use in calculations.

CORRESPONDENCE.

NITRIC ACID DISSOLVES TIN.

To the Editor of the Chemical News.

SIR,—Having been aware for a long time that a mixture of nitric and hydrochloric acids, in the proportions of 12 parts by volume of the former to 1 part by volume of the latter, diluted with 13 parts by volume of water, was capable of dissolving tin in very large quantity, I thought me of determining whether nitric acid alone had any solvent action upon that metal. Accordingly I mixed equal volumes of chemically pure nitric acid and pure water, and having poured into a clean test-tube a sufficiency of the mixed acids to ballast it and cause it to float upright in water, I set it afloat in that fluid, at a temperature of about $36^\circ \text{Fahrenheit}$. Taking care to keep the liquid cold, I added a fragment of pure tin of the size of a pin-head, which dissolved within an hour. Fragment after fragment dissolved in like manner, and the solution thus obtained was of a brilliant yellow colour, and perfectly transparent. Upon the application of a very gentle heat to the solution the colour disappears, and at the boiling-point the whole of the tin is precipitated as the hydrate of metastannic acid. To examine this nitric acid solution of tin it would be necessary first to pass through it a stream of dry and cold hydrogen in order to exsiccate the salt and free it from excess of acid, and afterwards to inquire into its properties. Would you oblige me by giving the above discovery publicity through your widely-circulated paper?

I have already mentioned the above facts to several chemists of my acquaintance, and all of them think the matter sufficiently important for notice in your columns. —I am, &c.,

GEORGE HAY.

31, Grove Street, Edinburgh.

SUPERSATURATED SALINE SOLUTIONS.

To the Editor of the Chemical News.

SIR,—I have to thank Mr. Tomlinson for the courteous tone in which he has criticised my last paper upon supersaturated solutions.

Just at present I have not time to answer his objections, but shortly I hope to do so fully. But with respect to the doubt which Mr. Tomlinson raises as to the non-supersaturation of the solutions experimented upon, I can only repeat what I have already twice stated (see *CHEMICAL NEWS*, vol. xxii., pp. 91 and 243), *i.e.*, that I took every conceivable precaution to ensure the solutions being fully supersaturated, and that I never accepted a result until I had proved this either by exposure to the air or by the insertion of a dirty rod, and, moreover, I almost invariably worked with such an excess of salt that some was thrown down in the anhydrous form during the boiling; hence this source of error was, I think, eliminated.

It would have been perfectly useless to have made experiments upon a solution which was not supersaturated. The discrepancy between my results and those obtained by Mr. Tomlinson must, as far as I can see, be explained in some other way.

In reply to Mr. Tomlinson's inquiry respecting the strength of the ethereal solutions—I may state the proportions were approximately one part oil to twenty of ether.—I am, &c.,

ARCHD. LIVERSIDGE.

Christ's College, Cambridge,
December 6, 1870.

MISCELLANEOUS.

King's College.—Mr. C. L. Bloxam has been appointed Professor of Chemistry in the room of the late Dr. W. A. Miller, and Mr. W. Noel Hartley has received the appointment of Demonstrator.

The Chair of Chemistry at St. Bartholomew's Hospital.—On Tuesday morning last, the candidates for the chemical chair at St. Bartholomew's Hospital were summoned to meet the House Committee of the Hospital. The following gentlemen attended:—Messrs. Dupré, Heaton, Mills, Russell, Maxwell Simpson, and Wanklyn. After waiting in the ante-room for about an hour and a half, the candidates were called into the board room one by one, seated on a high chair, and personally "interviewed" by the House Committee. Then Mr. Cross, secretary to the Hospital, read the letter of application, and the candidate was asked if he had anything to add to the letter. In most cases he was asked a variety of questions—"His age," "Whether he could manage boys," &c., and having replied to these interrogatories he was requested to withdraw. After a slight pause, Mr. Cross called in the successful candidate and communicated to the others the name of their more fortunate companion. The name announced was that of Dr. Russell, of St. Mary's Hospital. We are told that the usual steps in the election to the chemical chair at St. Bartholomew's are—recommendation by the Medical Committee of the Hospital, election by the House Committee, consisting of some thirty governors, and confirmation by the general body of governors, which numbers some 270 persons.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Zeitschrift für Chemie von Beilstein, No. 17, 1870.

Action of Phosphuretted Hydrogen upon Zinc-Ethyl.—C. Schultz-Sellack.—It is, says the author, a well-known fact, ammonia decomposes an ethereal solution of zinc-ethyl, forming zinc-amide. When phosphuretted hydrogen acts on an ethereal solution of zinc-ethyl, there is obtained a yellowish powder, which is not analogous to the zinc-amide just alluded to—viz., primary zinc-phosphine, but a substance containing carbon, so that the ether is simultaneously decomposed, as is also the case when phosphuretted hydrogen acts upon ether and chloride of cyanogen, as stated by MM. Darmstädter and Henniger.

Cyanchlorhydrine of Ethyl-Glycerine; and on Monochloro-Lactic Acid.—G. Glinzky.—This paper opens with a brief résumé of the author's researches on the action of hypochlorous acid upon chlorvinyl. When an aqueous solution of hypochlorous acid was treated with cyanide of potassium, a brown-coloured oily fluid, which is readily decomposed, was obtained, which appeared to be a fluid cyanaldehyde. This body gave, when treated with hydrochloric acid, a large quantity of sal-ammoniac, and, when afterwards treated with ether, yielded chloro-lactic acid. The probable mode of formation of this body is elucidated by a series of formulae too lengthy and complicated for us to quote. The next following section of this paper is devoted to the detailed description of the preparation of the cyanchlorhydrine of the ethylglycerine, which preparation is commenced with the reaction of hydrochloric acid upon chlorvinyl. This yields by fractional distillation several liquids, which boil at temperatures varying from 22° to 97°. When any liquid ceases to come over at that temperature another receiver is put on, and the distillation resumed at above 97°, and continued as long as the fluid collected in the receiver becomes emulsified when dry pulverised cyanide of potassium is added to it. After being properly purified (a somewhat lengthy and tedious operation), the resulting liquid is an oily fluid of agreeable smell, sweet, but burning taste, not capable of being boiled without decomposition even in vacuum, burning with a greenish coloured flame, soluble without producing any evolution of gas in nitric and hydrochloric acids; yielding, however, with the latter—chlorolactic acid. The formula of this body, cyanchlorhydrine of

ethylglycerine, is $C_8H_{12}ClNO$. The author then treats at length on the preparation of monochloro-lactic acid, and further states that chlorolactic acid, $C_3H_5ClO_2$, is a solid body, crystallising in irregular shaped foliated crystals, colourless and void of smell, readily soluble in water, alcohol, and ether, fusing at 81°. It is a rather strong acid, which dissolves zinc, sublimes with partial decomposition and yields with zinc two salts, viz: (1.) $(C_3H_5ClO_2)_2Zn + 3H_2O$, a solid, crystalline, efflorescent body, which, on being boiled with water, yields aldehyde; if heated above 100° the salt becomes brownish coloured, and at 190° it is decomposed, yielding aldehyde. (2.) $(C_3H_5ClO_2)_2Zn + 3H_2O$, obtained by dissolving zinc at 50° in the concentrated aqueous solution of the acid, exhibits small, irregular-shaped crystals. The silver salt of this acid, $C_3H_5ClO_2Ag$, is very difficult to prepare, since it is very readily decomposed by the action of heat and light. The salt crystallises in the shape of tufted acicular crystals. It is very prone to decomposition, for even when in hot water, it is resolved into carbonic acid, chloride of silver, and aldehyde.

Oxyisocaprolic Acid, Oxyisovaleric Acid, and Dipseudo-propyl-keton.—W. Markownikow.—The author, describes the following substances: oxyisocaprolic ether; $C_8H_{16}(C_2H_5)_2O$, a thickish, pale, yellow-coloured, mouldy-smelling fluid, boiling at about 202°—204°; is not acted upon by a concentrated solution of caustic potassa at 130°. This ether is best decomposed by alcoholic potassa. It then yields, after proper purification, the oxyisocaprolic acid $C_8H_{16}O_2$; $C(OH)CO_2H$, a solid body, crystallising in needle-shaped crystals, difficultly soluble in cold water, more readily so in alcohol and ether; fuses at about 110°. The barium salt of this acid $(C_8H_{13}O_2)_2Ba + 3H_2O$, is a crystalline, efflorescent body. Oxyisovaleric acid/pseudopropyl-hydroxalic acid, $C_6H_{12}CH(OH)CO_2H$, is soluble in ether, very deliquescent, and yields with barium an anhydrous salt, obtainable in semi-crystalline state. The formula of this salt is $(C_6H_{11}O_2)_2Ba$, soluble in alcohol. The formula of the silver salt is $C_6H_{11}O_2Ag$, difficultly soluble in cold water. Dipseudo-propyl-keton, $(C_3H_7)_2CO$, a fluid exhibiting a peculiar and strong smell. It is soluble in water and does not combine with sodium bisulphite. It boils at 123°. The author briefly states that oxyisocaprolic acid, when heated to 100° with fuming hydriodic acid, does not yield isocaprolic acid, but several iodides, amongst which is isopropyl-iodide.

Behaviour of Some of the Haloid Compounds of Ethylen and Propylen with Hydriodic Acid.—W. Sorokin.—The author first states that since Dr. Markownikow had proved that when hydric acids (haloid acids) combine with hydrocarbons, C_nH_{2n} , the haloid always prefers to combine with that C-atom which is bound to the smallest quantity of H; he therefore endeavoured to try to determine by experiments how, and in what manner, two haloids would simultaneously combine with an unsymmetrical hydrocarbon. This having been premised, the author describes in detail a series of experiments, which, however interesting, are not suited for abstraction.

Hydrocarbons, C_5H_{12} .—M. Lwow.—Of the hydrocarbons C_5H_{12} , three are theoretically known. Of these three, the second, obtained from amylalcohol, is somewhat better known. The formulae of these hydrocarbons are:—

The author has prepared the third member of this group—the tetramethylformen, a body answering to the formula— $2C(CH_3)_4 + Zn(CH_3)_2 = C(CH_3)_4 + ZnI_2$.

Zinc methyl is added drop by drop to the tertiary iodbutyl (the iodide of trimethylcarbinol); after a tedious process of purification there is obtained tetramethylformen, C_5H_{12} , a colourless, very mobile fluid, boiling at 95°, solidifying at -20° to a crystalline body, very similar to sublimed sal-ammoniac. This property of becoming solid and crystalline distinguishes this substance from hydride of amyl. The vapour density of this substance is = 2.493.

Haloid Compounds of Boron.—G. Gustavson.—Chloride of boron is readily prepared when boric acid anhydride is heated in a sealed tube for three or four days to 150°, with twice its weight of pentachloride of phosphorus. In addition to BCl_3 , there is also formed an oxychloride of boron. Trichloride of phosphorus does not act upon boric acid anhydride even when heated therewith to 200° for a period of three weeks. Chloride of boron can be distilled over sodium without decomposition, and when the temperature is raised to 150°, only a trace of free boron is separated. Pulverised metallic zinc does not act upon chloride of boron even to 200°.

Action of Phosgen on Zinc Methyl.—A. Butlerow.—The author first refers to some of his former experiments on this subject, stating that zinc methyl absorbs at the ordinary temperature very slowly, and somewhat more rapidly at 100°, phosgen, $COCl_2$, the result being the production of a crystalline compound, $[2Zn(CH_3)_2 \cdot C_2H_4OCl]$, which, on being decomposed by means of H_2O , yields trimethylcarbinol. But since simultaneously some acetic acid is formed, the author was induced to study the reaction alluded to more particularly. The greater portion of this paper is devoted to a detailed account of the experiments instituted for the special purpose of determining the moment when acetic acid is formed. The result of careful investigation in this direction was, however, negative. The author therefore comes to the conclusion that the acetic acid formerly noticed was due to the decomposition of trimethylcarbinol.

Constitution of Some Non-saturated Hydrocarbons.—A. Butlerow.—The introduction to this paper treats on the theory of the constitution and atomic and molecular structure of the hydro-

carbons, which are termed non-saturated. The greater portion of the essay is, however, devoted to a lengthy description of a series of experiments made with the view of elucidating the various theories which have been propounded on the subject.

Some of the Reactions Exhibited by Mercuriallyl.—M. Krawinsky.—The author states that at the suggestion of Professor Butlerow (University of St. Petersburg) he was induced to try to prepare some derivatives of the combination $(C_2H_5)_2Hg$, and also the bodies $(C_2H_5)_2Hg$ and $(C_2H_5)_2(C_2H_5)Hg$. The two last-named could not, however, be made. When a mixture of 15 grms. C_2H_5I , and 1½ grms. of acetic ether were heated with sodium amalgam, there was formed $(C_2H_5)_2Hg$, a volatile body exhibiting the smell of diallyl. If $Hg(C_2H_5)_2$ is heated to 100° in a sealed tube, along with an aqueous solution of KI, there is formed diallyl and Hg , $2C_2H_5HgI + 2KI = C_2H_5Hg + Hg + 2KI$. The author states further that when a mixture of $(C_2H_5)_2Hg$ and C_2H_5I is heated for three days with iron filings up to 100° in a sealed tube, the greater portion of the $(C_2H_5)_2Hg$ remains unchanged. With pulverised zinc the result is somewhat different, for when $Hg(C_2H_5)_2$ is treated with $Zn(C_2H_5)_2$, Hg is separated and mercurethyl formed without evolution of any heat or gas. The reaction is represented by—
 $2Hg(C_2H_5)_2 + Zn(C_2H_5)_2 = Hg(C_2H_5)_2 + Hg + C_6H_{10} + ZnI$.

Recovering of Iodine from Substances which Contain that Element.—Dr. F. Beilstein.—The author first states that when only iodine is present, the separation of that substance does not involve any difficulty, and therefore the process to be detailed refers to the separation of iodine from substances simultaneously containing bromine and iodine. The sufficiently concentrated saline solution (containing of course iodides, bromides, and perhaps chlorides) is acidified with sulphuric acid, and a current of nitrous acid gas, obtained by heating one part of starch (dry) with six parts of crude nitric acid, is then introduced into it. This operation requires cautious management, so as to obtain a regular supply of gas. The effect upon the solution is the separation of iodine, which is separated by filtration, as directed by Bunsen, washed with cold water, and dried over sulphuric acid. If it is desired to separate the bromine, if present, the filtrate is first heated in a basin, for the separation of any iodine which might have been left dissolved, and the fluid is then distilled, with a mixture of sulphuric acid and manganese.

NOTES AND QUERIES.

Orange-Lead.—Can any of your correspondents favour me with particulars of the manufacture of orange-lead, or of any published work from which such may be obtained.—J. DODD.

Separation of Tarry Matter from Gas-Water.—Can any of your readers inform me of a good mechanical method for separating suspended tarry matter from gas-water, of from 8° to 10° Twad., obtained by passing the water a number of times through the "scrubbers."—GAS ENGINEER.

Pyrotechny.—(Reply to Ernest J. Whiteford).—Consult Schubarth's "Standbuch der Technischen Chemie," vol. i. Under the heading of "Powder Manufacture," you will find a rather complete bibliography on your subject. You will find the work at the library of the Commissioners of Patents.

MEETINGS FOR THE WEEK.

MONDAY, 19th.—London Institution, 4. Dr. Odling, F.R.S., "On Chemical Action." (Educational Course.)

Medical, 8.

TUESDAY, 20th.—Institute of Civil Engineers, 8. (Anniversary.)

WEDNESDAY, 21st.—Society of Arts, 8.

Geological, 8.

THURSDAY, 22nd.—Royal, 8.30.

FRIDAY, 23rd.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

*. Our Publisher requests us to remind Subscribers that, if their Subscriptions for the ensuing year are sent to him in advance, the amount for one year will be 18s., no postage being charged; but if accounts are sent from the Office, the subscription will be £1.

Climax.—You will find the tables you require in the appendix to Miller's "Elements of Chemistry."

A Reader.—Write to the Secretary, Burlington House.

W. King, W. H. Dean, and others.—The work on "Dyeing" is not published yet; it will be announced as soon as it is ready.

A Constant Reader.—You need not hesitate to place dependence upon anything issuing from the principal of the firm you name.

J. Forth.—Your communication has been received.

W. F. Q.—Griffin's "Chemical Handicraft" will give you particulars of several of the furnaces.

L. M. Montgomery.—Your best plan would be to get a copy of the journal from which our notice was taken.

W. Hope.—Received, with thanks.

A. and M. Zimmerman.—Received.

J. Bottomley.—Your communication is unavoidably postponed till next week.

Rev. H. Highton, M.A.—Next week,

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I, Parts 1 and 2, price 36s., with more than 400 Illustrations.
 Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I, Part 3, price 33s., with more than 300 Illustrations.
 Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I, Part 4, price 21s., 300 Illustrations.
 Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I, Part 5, price 36s.
 Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870—1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Challenge to the World.—The Bristol Daily Times and Mirror, August 5th, has the following:—Messrs. J. C. Swan and Co., of 16, Queen's Square, in this city, have invented a pocket microscope, which is a marvel in all that such an instrument should be. It has great power, remarkable definition, and does not require focussing. The cheapness of the article will make it exceedingly popular when its merits are more widely known. It is called the "Bristol Microscope," and is a great credit to the inventor, as much for its extreme simplicity as its power.—The Western Daily Press says: The Bristol Microscope has a magnifying power of 20,000 times, &c., &c.—The Western Daily Telegraph says: The Bristol Microscope is the most compact and useful scientific instrument we have ever seen; it possesses extraordinary power, and is very easily managed, &c. The price of the Bristol Microscope is only 2s., or free by post, with printed directions, for 28 stamps.—Address, J. C. Swan and Co., Opticians, 16, Queen Square, Bristol.

THE CHEMICAL NEWS.

VOL. XXII. No. 578.

ON THE SEWAGE QUESTION.*

By EDWARD C. C. STANFORD, F.C.S.

(Concluded from p. 291).

Now, in estimating the value of a manure, Her Majesty's Commissioners attach little importance to farmers' certificates, but value it entirely by chemical analysis; this is the only fair way, because it shows exactly what it is worth in open market. But in comparing the value of irrigation with that of any chemical process dealing with sewage they bring in another and, I submit, an improper element, *i.e.*, the total profit of the farmer. This is unfair; the farmer buys his manure—say, made from bones, or, say, from excreta—by analysis at its market value, and his living is made out of what that investment produces from the land. The irrigationists have no right to put themselves in his place, reap his profits, charge themselves nothing for the sewage, and call that "making it pay." In one of the accounts quoted in Her Majesty's Commissioners' Report, I see the "right of shooting over the farm" actually entered as an irrigation profit! What will the farmer give for the sewage? Of course, much less than its analytical value, where, as with us, the water is not wanted. Farmers in the west of Scotland, although, no doubt, they can grumble as well as their English friends, very seldom have to grumble for want of water; and, at any rate, in their case, the value of the manurial matter will be in inverse geometrical proportion to the quantity of water it is dissolved in. I repeat geometrical, not arithmetical.

Our country has got into its sewage difficulties from the extreme persistence with which our engineers have clung to the idea that water is the great purifier. Hence, we began with the water-closet, combined with a cesspool, but the frightful results of this provision for the contamination of our drinking water were soon apparent. We could not stop there, we must go further, and convert the cesspool into a net-work of gigantic sewers.

Instead, therefore, of having one deep cesspool for each house, exposing a comparatively small surface, we now convert these into one shallow stream of large surface and underlying the whole city. Therefore, we can have no more wells; we must draw our drinking water from one great source far away from contamination.

Professor Corfield says our sewers must be porous to the drainage water above, and impervious below. Practically we know that all leak both above and below, the sewer gases diffuse upwards, and the sewer liquids find their way downwards.

Sewage gas will pass easily through brick walls, and the action of the sewage on the soil pipes diffuses them throughout the house. The British Association Committee says that no improvement has taken place in sewer ventilation.

I spoke of water in a former paper as "a mere carrier" of excretal matter; we find it now a most powerful diffuser, spreading far and wide its pollution.

It is idle to talk of carrying the sewage without decomposition to the land. Both the solid and fluid excreta are acid when voided; the former will remain several weeks without decomposition, and the latter several days; mix them or add water, and the mixture becomes alkaline in twenty-four hours, and in that time it absorbs oxygen rapidly, and is in a full state of decomposition. Again, the gases given off from this mixture are of the most dangerous character—light carburetted hydrogen is one; and this is one of the most diffusive gases with which we are acquainted, and

we cannot keep it and the poison germs which it diffuses out of our houses. The sickly odour of sewer gas is too well-known in all houses where there are water-closets.

Now I am quite prepared to admit that the water supply and the drainage arrangements are good and may be left for house-washing waters or surface drainage, and the slight amount of oxidation from the surface of the river may be sufficient to purify this. But when we look at this gigantic scheme as a scientific means of removing that small portion of dirt we call house-sewage, I say that our sanitary reformers have been looking at it through a water medium, and therefore seen it highly magnified. I only wonder that they have stopped here, and not always insisted on the removal of our house-ashes by the same means; the amount to be removed is about the same, and it would not pollute the water.

Let it not be supposed that the water-closet can ever be universal; all its evils are aggravated in hot climates, and in very cold climates it is impossible. The bursting of a soil-pipe in a dwelling house is a calamity which would soon put a stop to the use of the closets if it occurred often with us. Even Professor Corfield admits that the water-closet ought always to be ventilated by a window or an outside wall, and all know that a water-closet in a sick room in connection with a main sewer would be highly dangerous.

The healthfulness of irrigated fields is a much disputed question, but Professor Corfield easily dismisses it. I must, however, quote Dr. Spencer Cobbold, F.R.S., as the highest authority on the subject. In a pamphlet on "A New Entozootic Malady arising from the Utilisation of Sewage" he says—"The wholesale distribution of tape-worm eggs by the utilisation of sewage on a stupendous scale will inevitably tend to spread abroad a class of diseases some of which are severely formidable."

He states that, in Egypt, one-third of the population suffer from a small parasite in the blood; that this disease (Helminthiasis) is "terribly fatal," and that it has already been found by Dr. Harley in this country. He states his conviction that it is quite possible "twenty years hence, this parasitic malady may be as prevalent in this country as it is now known to be in particular sections of the African Continent." Coming from such an eminent authority the pamphlet presents a sufficiently terrible picture to make any sanitary reformer pause and consider if the country should be committed to even the bare possibility of such awful visitations. If many of our Ayrshire friends peruse it, they will resist the threatened inundation of Glasgow tape-worms as they would the most terrible army of invaders. And yet my friend Mr. Hope, V.C.,* of the British Association Irrigation Committee (and the most committed to irrigation), has the pluck to suggest "a convalescent hospital for diseases of the chest in the middle of his sewage fields, guaranteeing to the patients a certain number of irrigations in the month with genuine unadulterated London sewage," "where London beauties might come out to recruit their wasted energies at the close of the season, and, attired in a *costume de circonstance*, with coquettish jack-boots, would, perhaps, at times, listen to a lecture on agriculture from the farmer himself while drinking his cream and luxuriating in the health-restoring breeze." The pictures are somewhat different; Dr. Cobbold would, probably, consider this seeking the "diet of worms." The distinguished advocate of sewage irrigation is not the only "Hope" that has "told a flattering tale." On the other hand, Professor Corfield states that phthisis is greatly decreased by efficient drainage, *i.e.*, I suppose, increased by irrigation swamps.

In carefully reviewing the effects and defects of water carriage, I have been forcibly led to consider that to dry up the excreta is the safest, easiest, and best method of removal; it certainly is the only one by which we can ever expect to realise its full value. Now let us examine what these reports have to say against it.

I quote from his paper read before the Society of Arts, February 23rd, 1870.

* Read before the Glasgow Philosophical Society (Sanitary Section), Nov. 9th, 1870.

I scarcely know how to criticise the Royal Commission Report on this subject, because their objections apply only to the ash-pit and privy system as carried out in Lancashire, and we must agree with their conclusions, but the evidence does not in the least effect a proper dry closet system such as that I propose. In fact, they speak highly of some places where Moule's earth closets are used.

Professor Corfield, in speaking of the earth closet, admits that "with supervision the closets do not get out of order," but he has to admit, also, that they had to be substituted for water-closets, at "Dorset County School, because the water-closets always got out of order from things being put into them, and from the apparatus being broken," which, he says, was "because they were not simple and self-acting." But Dr. Buchanan describes the effect of the change as to have actually reduced cost of keeping off from £3 to 10s. per annum, and to produce manure worth 15s. per head per annum (which, however, Professor Corfield does not believe possible). A low fever, which visited the town two years following, never entered the school. The simple water-closets he recommends are used at Liverpool, but the supervision is undertaken and the rules enforced by the sanitary authority.

In one of the largest cotton mills in Scotland, the owners were obliged to give up the use of water-closets on account of their offensiveness. The cost of the pure water for the closets was £70 per annum; which was worse than lost, as it was returned to foul a pure stream. Dry closets have been substituted, the offensiveness indoors is entirely removed, the purity of the stream is maintained, and the product of the closets realise £150 per annum. Can any evidence be stronger?

As regards pollution of rivers, Dr. Frankland has shown by numerous comparative analyses that the sewage of so-called midden towns is even stronger than that of towns where water-closets are universal. Now this is a result which cannot surprise us when we remember that in all these towns the fluid excreta goes into the sewers; i.e. eight-ninths of the pollution, and unaccompanied by the large dilution of water from the closets. In fact, he adds, "connected as the middens usually are with the sewers, no inconsiderable proportion even of solid excrement, partly in solution and partly in suspension, does actually find its way into the sewerage system." One of the British Association Reporters instanced a town where the excreta was collected in ashes and then carted out to repair the roads. I need scarcely say that this is not the dry system we advocate, and I admit at once that if the urine is not to be collected, the dry system is a failure. Moreover, in all the midden towns referred to, from admixture with a large quantity of valueless material, a considerable amount of manure of a poor value is produced; the highest of which, that of Salford, only realises 7d. per head per annum, and 1s. 8d. ton, and in all cases the cost exceeds the produce.

Glasgow is better than this, say 2s. 6d. per ton, and 2s. per head. But even here, from the enormous quantity of ashes mixed with it, the police manure is obliged to be sold at a low price on account of the carriage. The whole system of removal is, however, infamous, and must be highly prejudicial to health. The mistake lies in the material used; instead of being the cheapest and most bulky, it should be the dearest and the least bulky. It is in this direction that I complain of there having been no investigations: we have a large choice of deodorisers, if we deal direct with the material, and without the intervention of water. For while the advocates of a wet system must necessarily use water, those who advise a dry system are not confined to the use of earth, which may not in the end be the cheapest.

The best is, I believe, what I have introduced under the name of X-charcoal, or charcoal derived from carbonised excreta. The quantity required is less than a quarter the amount compared with earth, and every city has its own source of supply; thus the two constant objections to the earth system are at once done away with.

In each of the closets I have a small earthenware urinal with a tube passing under the floor connected with the pan of the closet, and into this the chamber urine of each floor is emptied (this is kept entirely free from odour by two or three good sized pieces of wood charcoal). The total quantity to be dealt with is easily estimated, but as my former estimates, based on Lieurnur's estimate, differ from those adopted by Her Majesty's Commissioners, I append comparative statement, and also that of Professor Parkes, a high authority.

For 100,000 Persons, Average of all Sexes.

	Weight in cwt.			Value in £.	
	Lieurnur.	Parkes.	H.M.C.	Lieurnur.	H.M.C.
Fæces ..	78,000	50,919	64,937	5,800	4,263
Urine ..	484,000	814,732	840,637	35,800	28,140
Total ..	562,000	865,651	905,574	41,600	32,403

Per Head per Annum.

	Weight in cwt.			Value in shillings.	
	Lieurnur.	Parkes.	H.M.C.	Lieurnur.	H.M.C.
Fæces ..	0.78	0.50*	0.64	1.16	0.852
Urine ..	4.84	8.14	8.40	7.16	5.628
Total ..	5.62	8.64	9.04	8.32	6.480

Per Annum.

	Weight in tons.			Value per ton in shillings.	
	Lieurnur.	Parkes.	H.M.C.	Lieurnur.	H.M.C.
Fæces ..	3,900	2,546	3,246	29.74	26.26
Urine ..	24,200	40,736	42,032	29.54	13.38
Total ..	28,100	43,282	45,278	29.68	14.31

The calculations of value are mine, and are based on the usual estimate established by the last sewage commission at 8s. 4d. per head per annum as obtained from the analyses of sewage. This was made up on the analyses of Messrs. Lawes and Gilbert, each individual contributing per annum in—

Urine	11.32 lbs. ammonia =	7s. 3d.
Fæces	1.64 lbs. ammonia =	1s. 2d.
		8s. 5½d.

Taking Lieurnur's estimate of one cubic foot per head per annum solid, and 9 cubic feet liquid, rating also the relative value of 1 to 6, making 1s. 2d. per head for the former, and 7s. 2d. for the latter. Lieurnur's estimate allows a margin for loss.

I have calculated the values of Her Majesty's Commissioners' Report by taking the data in the table of the amounts of organic nitrogen and of phosphates, and valuing the former at £68 per ton, and the latter at £15 per ton, the values by which in the same report the manure of the A B C process is estimated.

The following shows the amounts in the table for 100,000 people:—

	Weight in cwt.			Per cent.		
	Organic nitrogen.	Potash.	Phosphates.	Organic nitrogen.	Potash.	Phosphates.
Fæces ..	957	649	1347	1.47	1.00	2.070
Urine ..	7531	2521	3380	0.89	0.30	0.402
Total ..	8488	3170	4727	0.937		0.522

It will be seen that the values given only allow 6s. 6d. per head per annum, or 14s. 4d. per ton. The value of the potash which I add to the table is, however, 3170 cwt. at 20s. = £63,400, and makes the total value = £35,573, or 7s. 1d. (7.114) per head, or 15s. 8d. per ton (15.68).

The magnesia and the other salts would no doubt bring up the value to the usual 8s. 4d., which, even at the high

* Parkes calculates the solid excreta of vegetarians at more than double this, or 12 ozs. per day.

quantities estimated, would give the manure an average value of 18s. 5d. per ton. The outside quantity to be removed, therefore, inclusive of all urine, cannot exceed 9 cwts. per head per annum, and its value cannot be less than 18s. per ton. Now, even at this high estimate the removal does not exceed that of the house-ashes. Taking the city through, for 500,000 inhabitants, the daily removal would be, at 300 days in the year (225,000 tons per annum), 750 tons. One high authority, Baron Liebig, estimates the annual value of the excreta per head (London sewage of 3,000,000 = £4,081,430) at 27s. 2d. This would make the excreta worth 60s. per ton. Even now, however, we find, where the earth system is thoroughly and efficiently carried out, Professor Corfield says the manure realises "above its possible value," and there can be no doubt whatever that if the profits of the farm are to be added, as in the case of the irrigators, the advantage would be enormously on the side of the dry system.

Taking however, the lowest computation, and putting the value of the excreta at 18s. per ton, every one must admit that it will pay to cart it away. X charcoal has a manurial value of £5 per ton, and an average composition—

Chloride of sodium*	4	×	1	=	4
Chloride of potassium	8	×	10	=	80
Phosphate of lime	25	×	15	=	375
Carbonate of lime	5	×	1	=	24
Carbonate of magnesia	5	×	5	=	25
Carbon	43	×	1	=	86
Silica	10	×	1	=	5

100 577 5
(Equal to £5 15s. 6d. per ton.)

This manure contains all that is necessary for plants except nitrogen. The effect of mixing one ton of it with one ton average excreta, is to obtain when dry 25 cwts. of manure having nearly the above composition, with the addition of nitrogen = 6 per cent sulphate of ammonia, and worth £6 per ton. The total gain being 25 cwts. × 6 = £7 10s. = 30s. per ton of excreta added, i.e., my original estimate of its value. Of course this can be fortified by re-use, or by adding the ammonia obtained in the distillation, to almost any extent. In fact, one of the analyses quoted in my former paper shows a charcoal retaining nitrogen equal to 105 per cent of sulphate of ammonia. But in addition to its actual manurial value, by re-burning at any rate that portion of the product which is required to replenish the closets and keep up the supply for the city, I obtain some new products of value, which have never yet entered into the calculation. These are acetate of lime, tar, and gas. The former arises from the acetic acid which comes over from the destructive distillation of the vegetable residues ejected in excreta; the two latter mainly from the fat passed in the excreta. I have before shown that we are only employers of fat as we are employers of nitrogen and phosphates, and though a portion is consumed, especially in winter, in supplying fuel to our bodies, yet a large portion is found in the excreta. This appears as tar in the distillation. This little item in Glasgow would amount to seven tons a days. The acetate of lime is as valuable as the sulphate of ammonia.

I need not here go further into the chemistry of the process, as that has been fully investigated, so far as known products are concerned, and an exhaustive series of analyses of the results has been published in my former papers submitted to the Chemical Section of the British Association, and published in full in the *CHEMICAL NEWS*. The analyses speak for themselves, and the statements have never been refuted.

Now, with regard to the healthfulness of the dry process of removal, I can find no evidence of any kind which in the least tells against it. The germ theory of

disease, now so generally believed in, is all in favour of a system which localises the poison and prevents its spreading. In opposition to water, which certainly spreads the germs, of that there is unlimited proof; the ordeal by fire to which I subject them must be absolutely destructive. No one knows exactly what the germs of cholera, scarlet fever, &c., are, but all admit them to be organic, and therefore all must admit that subjection to a red heat in an iron retort must destroy their vitality. Only last month, at a meeting of the London Association of Medical Officers of Health, Dr. Druitt, in his opening address, alluded to the prevalence of scarlet fever in London. "He believed scarlet fever to be emphatically a product of sewer gases." Dr. Rogers thought "scarlet fever to be more under control than any of the preventible diseases. The reason of its spreading so rapidly in some districts was that the excreta were not properly got rid of."

Dr. Tilley said that he had recently inspected forty or fifty houses into which there was a constant admission of sewer gases. (All this in London, where £5,000,000 have been spent on sewage with all the latest improvements, and gigantic pumps for lifting the sewage and leaving the gases behind.) Dr. Druitt said that sewers require disinfecting by drenching with carbolic acid in large quantity. Now, if it must be disinfected, how easy to add the disinfectant at the source.

I claim, then, the most extended benefit to health of towns by the adoption of this process.

As I propose, however, that the vault of a private house should only be emptied once a year, and as some may fear injury to health by allowing a ton or two of the X mixture to accumulate, I append an extract of a letter from W. Gilbert Hickey, Esq., C.E., of Calcutta, July 9, 1870, which should allay all fear on this head, and will show the extraordinary power of X charcoal. He says:—"I put this to a very crucial test. I placed an iron cylinder in my office, I perforated the bottom and placed a thin layer of charcoal poultrette, or poultrette coke, i.e., the residue left in the retort after carbonising excreta. I then sent to the public latrine, and had 1 cwt. of human ordure poured in. On top I placed a layer of poultrette coke, about two inches thick. It remained in the room for six weeks, and there was no nuisance of any kind."

Now, if 1 cwt. of human ordure can be kept in an office in Calcutta so long as this, completely deodorised by a slight layer of X charcoal, you may believe that nothing can be more inoffensive than a mixture of equal parts of each, such as I propose.

Now, as to the application to houses of the dry system, I deny that it requires any more supervision than the water-closet system.

One great advantage the householder has by using this process is, that if there should be any odour in his closet he has the remedy in his own hands. One of his servants has, perhaps, emptied some chamber slops into the urinal, without lifting the handle of the closet and allowing a charge of charcoal to fall. He has only to do this and the closet is at once deodorised. Now, with the water-closet, as the odour is due to sewer gas, the common method of letting down quantities of water only aggravates the evil, for the opening of the valve allows more gas to escape into the closet. For invalids the dry system is invaluable, and, in fact, absolutely necessary. I would request any who are not convinced of its value, or foresee any difficulty in applying it to towns, to read an American work on "Earth Sewage," by G. E. Waring, or inspect our arrangements at Dalmuir.

I understand that the householder is to have the use of the deodoriser for nothing, and the house to be visited by the "golden dustman," as I may call him, but once a year. The quantity of charcoal required being equal to that of the excreta removed. The method could be easily adopted to improve the removal of the town manure, with great advantage to health. The loss of Glasgow working men and women from ill-health and sickness must be

* Common salt itself an efficient disinfectant, always exists in X charcoal, but in variable quantity.

enormous, and the consequent loss of work of each person must be felt by the whole city in one form or other. Our town authorities are now, I believe, really awake to the alarming reports of the *Daily Mail* commissioner. I would quote, however, the best paragraph in Professor Corfield's report, and address them in the words of Mr. Rowe:—

"The man who in a crowded street is living in filth and breathing a putrid atmosphere, or who makes that street a receptacle for the offal which he casts from his dwelling, becomes an instrument of danger to his neighbour by spreading infection, and he not only hazards his own life but endangers that of others. The man who erects a flimsy edifice in a crowded thoroughfare, which in its falling may destroy life, should be prevented doing so, and he who constructs a house to let for profit, and pays no attention to those matters which are essential to comfort, but, on the contrary, so constructs it as to engender fever and endanger the lives of his tenants, all these are cases where, with propriety and in justice, the legislature ought to interfere, and to insist upon such a mode of construction as will not endanger human life."

ON FERMENTATION.*

By Professor A. W. WILLIAMSON, F.R.S.

(Continued from page 293.)

To return to our experiment. This glass vessel is now full of the gas, and by applying a taper which been lighted and blown out, but is still glowing, we shall find, on putting it into the jar, that it immediately ignites, which is the ordinary test of oxygen gas. By the aid of that theory, which has been discovered since the time of Liebig's suggestion, this one case of apparently anomalous action has been proved to be a perfectly normal and regular case of combination, and the same kind of thing has been done with regard to other cases of the same description.

A number of other processes which he classes with these may be shown to be due, not to any exceptional force that is at work in these cases, not to the force of any particular contagious action among chemical substances, but to the ordinary forces which induce chemical combination in the cases best known to us. Liebig's theory of contagious action has been alluded to, by a high authority in this country upon philosophical matters, as being a law of chemical action of a generality comparable to the law of gravitation in astronomy, and for that reason, if for no other, it must be of considerable importance to know what bearing our most advanced knowledge has upon that law. I dare say you see the connection between it and the case of fermentation. I will not go into particulars further than is necessary, in order to show you the general analogy.

First, I will take the case of alcoholic fermentation, as being the case best known. The ferment consists of little cells—which I hope I shall be able to show you at our next meeting—each one containing several chemical compounds, but itself a little living being. I will not say at present whether they are animals or plants. When you have these little organisms in water, or sugar, or in any moist substance, they are constantly, and of necessity, undergoing decomposition. You may arrest the decomposition by various agents, but if you do so, you kill them, or suspend their activity as yeast. No case is known to us of their acting like yeast without undergoing at the same time a process of chemical decomposition—being broken up into simpler substances than those which were contained in them. I pointed out, last week, that the sugar which is being decomposed by the yeast is by that process being broken up into substances which were contained in it, and that was what Liebig noticed. He said that this yeast is a substance which tends to decompose—it is

breaking up into simpler substances, and it induces in these particles of sugar which are in contact with it a decomposition similar to its own. The action which it is undergoing is contagious, and passes over to the contiguous particles of sugar; and he adduced cases like that of oxygen, as affording analogies among simple well-known bodies. I think what I have said with regard to the case of oxygen will be sufficient to show you that in those simple cases the idea of contagion is certainly not applicable.

A foreigner, who was describing some time ago the luxuriance of the crops in America, spoke of a bushel of *mice* being sown in a field, and a hundred bushels of *mice* being reaped. Of course, what he meant to say was *maize*, or Indian corn; but I am reminded of that anecdote by the necessity I am under for a moment of asking you to consider for a while some living beings under their general functions only. Suppose you had a bushel of actual English mice, and you put them into a granary full of corn. There clearly would soon be a great change. You are supposed to know nothing more about the particular organisation of these little beings than you know about the particular organisation of the little yeast cells. You know that these little things eat grain, and that in place of the grain which they eat there appear various products of decomposition, which can be easily collected and examined. They give off carbonic acid, and so forth, and if you examined the state of that granary after a time, you will find a chemical change, or rather a set of chemical changes, going on in the organisms of these mice. The substance of which they consist would be actually wasting away; they would be giving off carbonic acid, and nitrogenous and other products. And if you also examined the state of the corn which was there at first, you would find that it finally passed over into these same products; and I say that the theory of contagious action is as much applicable to the action of the bushel of mice in the granary full of wheat, as to the action of the yeast cells upon a solution of sugar. There is, in the one case, as in the other, an assimilation by the living organism of the material upon which it acts. The materials undergo certain changes, of which the general results are known to us, but of which the particulars are, I may say, in the main almost completely unknown. As to the processes by which these products are formed, it is as well to say that we do not know them. We know a little here and there about them, but it is nothing compared to our ignorance; therefore the resemblance is the more striking, and if we were to believe in the contagiousness of chemical action as applied to the case of the assimilation of sugar, by a ferment, and say the ferment gives off alcohol and carbonic acid, and that sugar is also resolved into alcohol and carbonic acid, we should really be describing in its general features a process analogous to that which I have just now mentioned; such a general analogy would be readily admitted by those who go into the particulars of the process, but I think it is of particular importance to have in addition to it something more practically useful to guide us in understanding chemical reactions. For that purpose I will take one or two chemical reactions of an exceedingly common kind. For instance, I will again take that chromic acid solution which I just now employed. Here you see is the green residue which I told you would be produced; I again take some of this chromic solution, throw some of it into water in this jar, so as to visibly tinge the water red; I will slightly acidulate the liquid by oil of vitriol, and I will then pour into the mixture (which I will describe as chromic acid dissolved in water, for the potash which was present is taken away from the compound by the sulphuric acid), a substance which I will merely describe as being greedy of oxygen, sulphurous acid. If Liebig's theory of contagious action were generally true in chemical action, you would, no doubt, expect that this sulphurous acid, in taking up oxygen, would make the chromic acid also take up oxygen. It is quite possible for the chromic acid to do so, for that

* The Cantor Lectures. Delivered before the Society of Arts.

blue substance which we had in this jar at first was nothing but chromic acid with oxygen added to it. But instead of this, we shall have at once a reduction of the chromic acid to deep green, which I dare say appears to you almost black. It is precisely the same thing as that pale, dirty green which you saw before, but in its concentrated state. There is no oxygen taken up by the chromic acid, but it at once loses oxygen. This sulphurous acid wanted to combine with oxygen, and it tore away at once some of the oxygen from the chromic acid, and there was in this chromic acid a process, not similar to that which the sulphurous acid underwent, but a process precisely opposite to it—one combined with oxygen, while the other lost oxygen—and if you examined the liquid, you would find that the sulphurous acid which took part in the process, and has taken up oxygen, is now in the form of sulphuric acid. Again, I have here some granulated zinc, which will very easily evolve hydrogen, particularly when its activity is stimulated by throwing a little copper vitriol on to it. After adding a little water, I will throw in a little oil of vitriol, so as to get an evolution of gas. Then I have here a solution which I think must look black to you, except at the edges, which is a solution of a beautiful salt called permanganate. It is used for deodorising certain fetid waters, and I might compare it to the chromate I was using just now. It consists of an acid of the metal manganese. If I throw some of that into the mixture which I have just prepared, and leave it for a short time, and then examine it, we shall find that, instead of being induced to give off hydrogen like the other body, which is doing so vigorously, we shall find it will do the opposite, and will combine with hydrogen; and the colour which belongs to it, and which can be recognised so easily, will disappear, because hydrogen will be taken up by its oxygen, and it will be reduced and brought down to a substance containing comparatively little oxygen. There, again, as in the previous case of the chromic acid, we find that there is a kind of chemical polarity in the general mode of action, that the one substance acted upon does precisely the opposite of the other. There is no tendency in this case to do the same thing, but the two substances acting upon one another do precisely the opposite, the one taking up what the other loses. Not only is that the case in the instance of the action which I have mentioned here, but in a great number of other cases of considerable interest and importance—bodies which act chemically with considerable energy when allowed to do so, are prevented by others from so doing when those others are trying to do the same thing. If, for example, we put metallic copper into nitric acid, the copper would dissolve with immense energy; it would undergo what I might call a process of combustion. Again, if I put mercury in contact with the acid, the same thing would occur; it would be dissolved almost as rapidly as the copper. But if I put the two together into nitric acid, the copper prevents the mercury from undergoing combustion; and so far from encouraging it to do the same thing, it actually takes from it the power which it possessed before of undergoing a combination of that kind. And more than that, if I take mercury which has been burned—a solution of mercury in the form of corrosive sublimate—and put copper into it, the copper will actually unburn it, or make it come back again from the point at which it had got, and throw down the metal. You can see the process which takes place; on putting a strip of clean red copper into the solution it becomes grey, and throws down the mercury from the solution. So far from encouraging the mercury to oxidation, it makes it do the opposite to that which it otherwise had a tendency to do.

Again, I will take some of this solution of copper—it ought to be some of the very solution which is being made here, where copper is being dissolved at the expense of mercury—and if I put into it a piece of common iron, perfectly clean and white, it will very speedily combine; and I cannot express its functions in combining better than by saying that it will make

copper uncombine, for the copper which was burnt is now being unburnt.

If we go carefully, with the knowledge of their particulars, through the best known chemical processes, we find that there is, as a rule, a force at work which I might describe as polarity—a tendency among contiguous particles which are acting on one another to assume functions which can be best characterised as being opposite to one another. Whatever the one is doing, the other is doing as nearly as possible the very opposite of it, and any tendency to do like work I know not of. There are, however, cases which would appear to be favourable to the notion of contagious chemical action. If I blow out that gas-burner, still letting the gas escape, and then bring near to it a burning splint, it will set fire to the gas, and the same with a candle-wick if I bring close to it a burning match—the match, which is burning, communicates to the wick the process which it is undergoing—but the explanation is this, it does so merely because of the high temperature which it has attained. If by any other process, such as concentrating the rays of a powerfully-heated surface by means of a lens, I raise the temperature of the gas to that point at which it is capable of combining with the oxygen of the air, it will do just as well. The accident that the high temperature is communicated by the burning splint has nothing to do with the process.

There is one other remarkable instance which I must give you, to show you the difficulty in some cases of analysing these phenomena. It is the case of the metal platinum, which I can hardly describe better in general terms, as regards its properties, than by comparing it to gold. It is what is termed a noble metal; it does not dissolve in any ordinary acid; you might boil platinum in nitric acid for any length of time and it would not dissolve. On the other hand, silver is a metal which dissolves readily in this acid, and if you melt silver and put platinum into it, it will also melt, and you obtain a compound of the two metals mixed pretty uniformly together. It was noticed that when such a button of platinum and silver is put into nitric acid, not only does the silver itself dissolve, as you would expect, but some of the platinum also dissolves with it; not the whole, but a portion. That seems, at first sight, favourable to the theory of contagion; it seems natural to suppose that the silver in dissolving has communicated the same tendency to the platinum, and made some of it dissolve. But that explanation will not do, and for this reason. When platinum is combined with anything else, I care not what, its properties are not the same as when uncombined. The very essence of chemical combination is that the particles which are in intimate contact unite, and that the compound possesses different properties from the original elements. We know that metals combine with one another; there are many cases known to us of the forcible union of metals, and we have no right to suppose in any case, unless we have actual proof of it, that a metal is present in such a compound with its ordinary properties. Therefore, it is not free platinum, but a compound of platinum and silver which dissolves, and there are some compounds of platinum which dissolve in water, and others which dissolve in nitric acid, so that this process has really nothing to do with contagious action.

(To be continued).

London Institution.—At a meeting of the Board of Management of this Institution on Wednesday, Dr Henry E. Armstrong was appointed Professor of Chemistry, an office once held by Mr. W. R. Grove, Q.C., and subsequently by Mr. J. Alfred Wanklyn. Dr. Armstrong studied chemistry under Professors Hofmann, Frankland, and Kolbe, and has been associated with Dr. Frankland and the late Dr. Matthiessen in original researches. We understand that classes for Practical Chemistry will be formed at this Institution early in the new year.

CHEMICAL TABLES ACCORDING TO THE THEORIES OF MODERN CHEMISTRY.*

ON A METHOD FOR THE DETERMINATION
OF SULPHUR IN COAL GAS.*

By A. VERNON HARCOURT, M.A., F.R.S., Sec. C.S.

THE apparatus on the table represents the result of a number of experiments on the determination of sulphur in coal gas, and provides, I believe, a means of making this determination easily and accurately.

But since its completion a new method of determining sulphur has been published and brought into use by the gas referees, and as this method is certainly superior in simplicity, and may be superior in other respects to that which I have devised, I feel some hesitation in laying any claim to the attention of the Section. However, the problem to be solved is one of so much difficulty and so much importance, that I will venture to describe very briefly the process which is here in operation.

Some difference of opinion exists as to the statement of the problem. Do we desire to know the total amount of sulphur in the gas analysed, or the amount which is converted into sulphur acids when a jet of gas is burned in the air? On the one hand, the practical object being to ascertain the injury to which we are liable from gas burned in the ordinary way, and the only sulphur compounds formed by burning gas, which are known to be injurious, being the sulphur acids, a method in which the acids formed by a jet of gas burning in the air are determined appears the most appropriate. On the other hand, we can hardly expect to arrive at definite and concordant results, except by determining the total amount of sulphur, since the part, if any, that commonly escapes unburnt, is likely to vary with the burner employed. I believe, however, that it will be found that this distinction is not a very real one, but that in a jet of gas which is well supplied with air, $\frac{1}{80}$ ths of the sulphur is oxidised.

In my apparatus I use a small Bunsen's burner, which gives a flame, scarcely visible in the daylight, of three-quarters of an inch in length when burning at the rate of a quarter of a cubic foot per hour. The gas is supplied by means of an aspirator with between 20 and 30 times its volume of air. A funnel placed at the top of the cylinder in which the gas burns admits the air through holes in its neck and distributes it down the sides of the cylinder, while the products of combustion and the excess of heated air are withdrawn from within the funnel through a tube rising from the bottom of the cylinder. This tube fits loosely into another tube, which passes through an india-rubber plug closing the cylinder, and is attached to a system of bulbs, through which are driven the air in which the gas has burned, and the liquid used to wash it. From the bulbs they pass into a two-necked receiver placed over the cylinder, whence the air escapes into the aspirator, while the liquid descends through a small tube to the bottom of the cylinder and repeats its course.

The liquid is an ammoniacal solution of copper. The ammonia serves, as is well known, to aid in fixing the sulphur compounds, while the copper determines, in presence of the excess of air, the oxidation of sulphite to sulphate. The activity of copper in this respect may readily be proved by pouring into each of two large bottles a few drops of

ammonia and of sulphurous acid, and adding, in one case, a drop of a solution of any copper salt. After shaking both bottles for a minute or two to bring the liquid and air contained in them into contact, if some dilute sulphuric acid is poured into each, and then some solution of iodide, it will be found that in one case plenty of sulphurous acid remains, but that in the other, when the drop of copper solution was added, all has disappeared.

When coal gas burns, the greater part of its sulphur seems to be oxidised completely to sulphuric acid, but a part of it only to sulphurous acid, and it may well happen that some of this sulphurous acid, after being arrested by the ammonia, may be disengaged again by the great excess of carbonic acid by which it is accompanied, and may finally escape from the solution. Once converted into sulphate it is safe.

The air which enters the cylinder has passed first through a large Woolfe's bottle containing pumice and ammoniacal solution of copper, the latter rising three or four

inches from the bottom of the bottle, the former to the top. Before each experiment 50 c.c. of strong ammonia is poured into the bottle. This arrangement serves to keep up the supply of ammonia in the apparatus, and to purify the air from traces of sulphurous acid or sulphuretted hydrogen. To trust to the purity of the air, even in rooms which are not chemical laboratories, appears to be very hazardous, when we consider that the volume passing through the apparatus in each experiment is 50 cubic feet, or more, and that $\frac{1}{50}$ th of a grain of sulphur

* Read before the British Association. Reprinted, by permission, from the *Journal of Gaslighting*.

in this volume would be reckoned as an additional grain in 100 cubic feet of the gas.*

When about 2 cubic feet of gas have been burned the operation is stopped, and the liquid withdrawn through two nipper-taps; a charge of water is sent round the apparatus by the aspirator, and drawn off into the same vessel as the original liquid, the drainage is sufficiently complete for a second washing to be hardly needed. It is convenient to get rid of most of the ammonia and part of the water by evaporation before precipitating with barium chloride.

To test the trustworthiness of the results obtained by this method, I have substituted for the lamp a tube, through which was passed, for as many hours as the process ordinarily occupies, a current of carbonic acid which had bubbled through a very dilute solution of sulphurous acid, whose strength was determined before and after the experiment. It was found that within the limits of error likely to occur in estimating the strength of the solution of sulphurous acid, the weight of sulphate of baryta obtained corresponded to the sulphurous acid which had passed out of the solution. It was in making these experiments that my attention was forcibly directed to the need of purifying the air, for I found at first that more sulphate of baryta was precipitated than the sulphurous acid could furnish. The air had passed through a bottle containing pumice and permanganate of potash, but the contents of the bottle had become dry, and, therefore, inoperative. In subsequent experiments the air was more efficiently purified, and the weight of sulphate of baryta was no longer in excess.

The completeness of the washing effected in the apparatus has also been tested by interposing a second set of bulbs, with a charge of ammoniacal solution of copper, between the aspirator and the apparatus. The liquid from these bulbs has always yielded a trace, but a mere trace, of sulphate of baryta.

Lastly, I have made a number of simultaneous determinations of the same sample of coal gas.

I will give the results of four pairs of determinations of samples of gas supplied by the Oxford Gas Company, made on consecutive days:—

	Sample	A	B	C	D
Grains of sulphur in 100 cubic feet.	1.	21.0	19.9	20.1	20.8
	2.	21.4	20.0	20.3	20.5

Since completing this apparatus I have made some experiments with a view to a more complete purification of coal gas from sulphur. Two pairs of analyses of the purified gas gave the following numbers:—

	Sample	A	B
Grains of sulphur in 100 cubic feet.	1.	4.54	4.49
	2.	4.57	4.54

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 15th, 1870.

Professor FRANKLAND, F.R.S., Vice-President, in the Chair.

The following gentlemen were elected Fellows:—P. T. Atkinson, R. Koma, J. F. Stark.

Mr. PERKIN, F.R.S., read a paper "On Some New Derivatives of Coumarin." The author succeeded in obtaining the following new bodies:—

Dibromide of coumarin ..	$C_9H_6O_2Br_2$
Dichloride of coumarin ..	$C_9H_6O_2Cl_2$
α Bromocoumarin ..	$C_9H_5BrO_2$
β Bromocoumarin ..	$C_9H_5BrO_2$
α Chlorocoumarin ..	$C_9H_5ClO_2$
β Chlorocoumarin ..	$C_9H_5ClO_2$
α Dibromocoumarin ..	$C_9H_5Br_2O_2$
β Dibromocoumarin ..	$C_9H_5Br_2O_2$
Tetrachlorocoumarin ..	$C_9H_2Cl_4O_2$
Coumarilic acid ..	$C_9H_6O_3$
Bromocoumarilic acid ..	$C_9H_5BrO_3$
Sulphocoumarilic acid ..	$C_9H_6O_2SO_3$
Disulphocoumarilic acid ..	$C_9H_6O_2S_2O_3$

Dibromide of Coumarin.—A solution of coumarin in carbon disulphide is mixed with a similar solution of bromine, and the mixture, after leaving it to stand for twelve hours, allowed to evaporate spontaneously. When dibromide of coumarin is treated with an alcoholic solution of potassic iodide, it becomes brown, and on evaporation deposits needles, apparently consisting of a mixture of iodine and coumarin crystals, α bromocoumarin. By heating two parts of bromine with one part of coumarin (both dissolved in carbon disulphide) in a sealed tube for three or four hours to about 200° C., monobromocoumarin is obtained. In this reaction dibromocoumarin is undoubtedly first produced, but at the high temperature employed it is decomposed by the hydrobromic acid produced, losing half of its bromine, thus:—

Dibromocoumarin.

Bromocoumarin.

The bromocoumarin obtained by this process sometimes crystallises from alcohol in long slender needles. These, however, on standing in the mother-liquor for a few days become short and hard, like those described in a previous paper.

However, a still more simple process for the preparation of bromocoumarin is to decompose the dibromide of coumarin with alkalis, the following reaction taking place:—

Dibromide of
coumarin.

Bromocoumarin.

From the difference in the appearance of the products obtained by the two processes, Mr. Perkin was at first inclined to think they were isomeric forms of bromocoumarin; but as the fusing points are nearly identical, as are also the products of decomposition, these variations must be ascribed to the presence of small amounts of impurities.

α Bromocoumarin, when left in contact with cold alcoholic ammonia, decomposes with formation of ammoniac bromide, and a non-crystalline sticky mass, easily soluble in water. Heated with potassic hydrate it yields potassic bromide and a new acid.

It decomposes when heated with potassic cyanide and alcohol in a sealed tube, forming a brown solution, from which water throws down a drab-coloured amorphous precipitate.

When heated to 200° C. in a sealed tube for five or six hours, slight decomposition takes place, with formation of hydrobromic acid. A similar change takes place if water be used instead of alcohol.

α Dibromocoumarin.—On a previous occasion, Mr. Perkin prepared this body by heating in a sealed tube to 140° C., a mixture of one part of coumarin, two parts of bromine, and four or five parts of disulphide of carbon. He afterwards found, however, that this process is greatly improved by the addition of iodine to the mixture, as it is then only necessary to heat the sealed tube for four or five hours in a bath of salt and water to complete the reaction.

The product is then freed from disulphide of carbon by evaporation, and from iodine by means of potassic iodide, and finally purified by two or three crystallisations from alcohol.

* Dr. Angus Smith has found the amount of sulphurous acid in Manchester air to attain sometimes as much as 1-1000th per cent. Such air admitted without purification would affect a sulphur test to the extent of 16 grains in 100 cubic feet of gas.

The fusing-point of this substance is 183°C. , and not 174°C. , as has been previously given.

β Bromocoumarin.—It will be remembered that the sodium derivative of the hydride of salicyl when digested with acetic anhydride yields ordinary coumarin. It therefore appeared to be of interest to treat the sodium compound of brominated hydride of salicyl in a similar manner to see whether a brominated coumarin could be obtained. This was found to be the case. The hydride of sodium bromo-salicyl when submitted to the action of acetic anhydride, yields a quantity of hydride of bromo-salicyl and a body which, when crystallised from alcohol, yields colourless flat prisms, the analysis of which showed it to be monobromocoumarin, $\text{C}_9\text{H}_5\text{BrO}_2$. It greatly differs in properties from the bromocoumarin previously described, its fusing-point being 160°C. , or 50° higher, and when boiled with alcoholic or aqueous potassic hydrate, it does not decompose with formation of potassic bromide, but simply dissolves like ordinary coumarin.

β Dibromocoumarin.—On treating the hydride of sodium di-bromosalicyl with acetic anhydride in exactly the same manner as for the preparation of β bromocoumarin, a beautifully crystalline product is obtained, of the composition $\text{C}_9\text{H}_4\text{Br}_2\text{O}_2$.

It is not the same body as that obtained by acting on coumarin with bromine and iodine. It fuses at 176°C. , and is not decomposed by boiling with a solution of potassic hydrate. Mr. Perkin has, therefore, designated it as β dibromocoumarin.

Dichloride of Coumarin.—A solution of coumarin in chloroform absorbs chlorine gas, only minute quantities of hydrochloric acid being formed. On allowing the solution to evaporate spontaneously after the chlorine has been passed through it for an hour or two, a syrupy product is obtained very like new honey. This is the dichloride of coumarin. From its products of decomposition there can be no doubt that it possesses the formula $\text{C}_9\text{H}_6\text{O}_2\text{Cl}_2$.

On keeping, it appears to decompose, when heated it gives off hydrochloric acid, and when distilled is converted into chlorocoumarin. With alcoholic potash it decomposes in the same way as the dibromide.

α Chlorocoumarin.—A mixture of one part of coumarin and three parts of pentachloride of phosphorus, when mixed and heated in a retort placed in an oil-bath, slowly react upon each other as the temperature rises, and when the oil has reached about 200°C. , the product becomes a dark brown liquid. During this reaction a volatile liquid, consisting chiefly of bichloride of phosphorus distils over. The contents of the retort after treatment with water become a pasty mass of crystals, which is first purified by distillation and then by several crystallisations from alcohol. Its analysis gave the formula $\text{C}_9\text{H}_5\text{ClO}_2$.

It is very curious that if half the amount of pentachloride of phosphorus mentioned above be employed, the product of the reaction suddenly carbonises—sometimes when the oil-bath is at a temperature as low as 153°C. , whereas, with the excess of pentachloride, it may be heated in an oil-bath standing at 200°C.

α Chlorocoumarin may be easily prepared by treating the dichloride coumarin with alcoholic potash in exactly the same manner as described for the preparation of α bromocoumarin. It fuses at 122° to 123°C. , and when heated possesses an agreeable aromatic odour.

Tetrachlorocoumarin.—Chlorine gas, when passed through a solution of coumarin and iodine in tetrachloride of carbon, is rapidly absorbed, hydrochloric acid being evolved. If the gas be passed for two or three hours a quantity of a reddish body separates; on evaporating the product so as to separate the tetrachloride of carbon, an oily residue is obtained, the red substance having fused with the impurities. On mixing this with alcohol it soon becomes a white paste. On pressing this in a small linen bag a white product is obtained, which is further purified by being several times crystallised from spirit. The num-

bers of the analysis lead to the formula $\text{C}_9\text{H}_2\text{Cl}_4\text{O}_2$. It fuses at 144° to 145°C.

Coumarilic Acid.—a bromocoumarin, when boiled with a solution of potassic hydrate, decomposes, yielding potassic bromide and the salt of a new acid. To prepare this acid in a pure state it is best to proceed in the following manner. A quantity of pure α bromocoumarin is mixed with an excess of the ordinary solution of potassic hydrate. On heating this mixture the bromocoumarin gradually dissolves, but on reaching the boiling point the solution rapidly becomes a pasty crystalline mass. Sufficient water is then added to dissolve this, and the boiling continued for about an hour. The solution on cooling deposits the potassic salt of the new acid in small needles. To obtain the acid from this salt it is purified and then dissolved in water, and hydrochloric acid added in excess. The new acid is then thrown down as a snow-white crystalline precipitate, which is purified, first by washing with water on a filter and then by crystallisation from boiling water. Its formula is $\text{C}_9\text{H}_6\text{O}_3$, as the following comparisons will show:—

	Theory.		Experiment.	
			i.	ii.
C_9	108	66.67	66.46	66.72
H_6	6	3.70	3.86	3.67
O_3	48	29.63		
	162	100.00		

This acid, which Mr. Perkin proposes to call coumarilic acid, fuses at 192° to 193°C. It distils without leaving any residue, but decomposes partially, with formation of an oily body smelling like naphthalin. When gently heated it sublimes. It is monobasic. Mr. Perkin has prepared its salts of the alkalies and the alkaline earths as well as those of silver, lead, mercury, and iron.

Bromocoumarilic Acid.—It is prepared like the above acid, but substituting α dibromocoumarin for bromocoumarin. It possesses the formula $\text{C}_9\text{H}_5\text{BrO}_3$. Its fusing-point is 250°C. It forms, like coumarilic acid, well-defined salts with ammonium, soda, &c.

Sulphocoumarilic Acid.—On digesting a mixture of about one part of coumarin and five parts of fuming sulphuric acid in the water-bath for an hour or two, the product will be found to be perfectly soluble in water. This, when diluted and neutralised with baric carbonate, yields, besides baric sulphate, a soluble salt, which, when evaporated, crystallises in tufts of transparent prisms. To obtain the new acid from this salt it is dissolved in water, and sulphuric acid added in exactly the quantity necessary to precipitate all the barium as sulphate. The solution is then filtered and evaporated, first over the water-bath and then *in vacuo*. In this way the acid is usually obtained in needles easily soluble in water.

From the analysis of its salts the formula of sulphocoumarilic acid when anhydrous is $\text{C}_9\text{H}_6\text{O}_3\text{SO}_3$.

Mr. Perkin has prepared ammonic, potassic, acdic, baric, and stromtic sulphocoumarilates.

Disulphocoumarilic Acid.—On heating a mixture of about eight parts of fuming sulphuric acid and one part of coumarin to a temperature of 150° or 160°C. for an hour or two, the product will contain two sulpho-acids, viz., sulphocoumarilic acid and disulphocoumarilic acid. On treating this with baric carbonate in the usual manner the solution will contain the barium salts of these two oxides. To separate them the solution is evaporated to dryness, and treated with warm water. This removes the, baric sulphocoumarilate, leaving the less soluble salt of the new acid behind. This salt has the formula $\text{C}_9\text{H}_4\text{O}_2\text{Ba}''2\text{SO}_3$.

From what has been said of the above chlorine and bromine derivatives, it is evident that the chlorine or bromine must be related to different carbon groups, according as the product belongs to the α or the β series. In the latter case it is contained in the C_6 group as these bodies are produced from the brominated hydride of

salicyl. The bromine in the bromocoumarin obtained from these bodies by means of acetic anhydride is not attacked by boiling with potash. In the α series the Br or Cl must be connected with the carbon of what may be called the acetic residue. The bodies of this series are easily decomposed with alkalis. In α dibromocoumarin one-half of the Br appears to be in union with the C₆ group, and the other with the acetic residue. α bromo- and chlorocoumarin, from their yielding with alkalis coumarilic acid, seem to be bromides and chlorides of an acid radicle (coumarilyl). But the ammoniac coumarilate on boiling with potash does not give the acid. It may, therefore, be that coumarilic acid is not a true acid containing the group COHO, but is only coumarin with one of its H replaced by HO.

Fittig and others consider coumarin as the glycolide of oxyacinnamic acid. If this were the case it certainly would be an anomalous one, as it may be kept dissolved in caustic alkali for months without formation of appreciable quantities of coumaric acid; neither does it form an amide when treated with gaseous ammonia. Whereas, the corresponding glycolide of salicylic acid is converted into a salicylate as quickly as it dissolves in an alkali.

The next communication was by Dr. DEBUS, "On the Formula of Glyoxylic Acid."

Dr. Debus showed that this acid ought to be written C₂H₂O₃, and not C₂H₄O₄. He considers it in reality to be the aldehyde of oxalic acid. Among other reasons for this view he quoted its behaviour towards bisulphites. Dr. Odling was of the same opinion. He sees the aldehydic character of glyoxylic acid in its property of easily combining with an atom of water, or of ammonia, or of ethyl, &c. Mr. Perkin thinks the second formula the right one. Among other evidences for the correctness of this view, he mentioned the fact that glyoxylic acid, when treated with phosphoric pentabromide, takes up three atoms of bromine in the place of three of hydroxyl, thus:—

Were glyoxylic acid constituted as represented by Dr. Debus, then, argued Mr. Perkin, there was every reason to believe that when acted upon by phosphoric pentabromide it would be entirely broken up, thus:—

CORRESPONDENCE.

MAGNETIC POWER OF A BATTERY.

To the Editor of the Chemical News.

SIR,—In your "Correspondence" of CHEMICAL NEWS, vol. xxii., p. 272, allusion is made to the statement in text-books of electricity that the intensity of the current is greatest when the external resistance is equal to the internal. As a proof is not usually given, the following, which I think will be found satisfactory, may be of use to some of your student-readers. Suppose we have m cells, the electromotive force of each being E , and the internal resistance of each being R . Suppose the cells are so distributed that we have x rows, each row consisting of y cells, in each of the rows the positive elements being connected one with another, and also the negative elements being connected one with another. If, then, the external resistance be r , and the intensity of the current I , we have, by Ohm's law,—

$$I = \frac{x E}{\frac{x R}{y} + r}$$

Also, $x \cdot y = m$. Differentiate with respect to x , and we get—

$$\frac{dI}{dx} = \frac{E r + x^2 \frac{dy}{dx} E R}{\left(\frac{x R}{y} + r \right)^2}$$

For a maximum or minimum value of I , the condition is—

$$E r + x^2 \frac{dy}{dx} E R = 0$$

Substituting for $\frac{dy}{dx}$ its value $-\frac{y}{x}$, we get as the condition

$$r = \frac{x R}{y}$$

That is, the external resistance is equal to the internal. If we differentiate again, we obtain—

$$\frac{d^2 I}{dx^2} = \frac{E R \left(x \frac{dy}{dx} - 1 \right) \left(3r - \frac{x R}{y} \right)}{\left(\frac{x R}{y} + r \right)^3}$$

Substituting for $\frac{dy}{dx}$ its value $-\frac{y}{x}$

$$\frac{d^2 I}{dx^2} = -\frac{2 E R \left(3r - \frac{x R}{y} \right)}{\left(\frac{x R}{y} + r \right)^3}$$

Suppose, now, that $\frac{x R}{y} = r$; and the expression becomes—

$$\frac{-4 E R r}{\left(\frac{x R}{y} + r \right)^3}$$

That is, when the external resistance is made equal to the internal, the value of $\frac{d^2 I}{dx^2}$ is negative, which shows that under this condition the value of I is a maximum.—I am, &c.,

JAMES BOTTOMLEY.

Queenwood College, near Stockbridge,
Hants, Dec. 8, 1870.

CHEMICAL PROBLEMS.

To the Editor of the Chemical News.

SIR,—I observe in your review of Professor Thorpe's work on "Chemical Problems" a slight inaccuracy, which I hope you will allow me to point out. You state you "believe that Dr. Roscoe was one of the first to recognise the value of such questions." I, on the contrary, believe that I was the first to introduce them. In 1851 the first edition of my "First Step" appeared, which was the first work, as far as I am aware, devoted to chemical problems, and I had for some years before the publication of it employed the problems in my classes. When I had the work ready for the press I sent a copy of the arithmetical questions to my friend Dr. Frankland, who was then Professor of Chemistry at Owen's College, and he wrote to ask my permission to make use of them in his classes before the work was published, which I readily granted, and he and Dr. Lyon Playfair were the first to employ them after its publication. In my "Second Step," which appeared in 1863, which is prior to the publication of Dr. Roscoe's "Chemistry," I gave an advanced course of chemical problems.

It has been a pleasure to me to see the problems so extensively employed, as I believe they have effected some improvement in chemical examinations, and I hope the new class of questions I have given in the last edition of my "Qualitative Analysis" will be adopted, as I believe they would put a stop to the cramming system, which is

now unfortunately so prevalent, and which is so ruinous to all real mental culture.

But the examinations in practical chemistry are, I think, in a far worse position at the present time than the written examinations, and I think if you would allow an interchange of opinions through the columns of the CHEMICAL NEWS on this subject, it would conduce very much to the progress of the science. I will, with your permission, commence this interchange in another communication.—I am, &c.,

ROBERT GALLOWAY.

Royal College of Science, Dublin,
December 19, 1870.

THE REACTION BETWEEN WATER AND NITROGEN TETROXIDE.

To the Editor of the Chemical News.

SIR,—From Mr. Vernon Harcourt's letter, which appeared in the CHEMICAL NEWS, vol. xxii., p. 286., it seems that that gentleman does not raise any objection to the validity of the method of determining nitric oxide employed in my recent investigation.

The exact nature of the chemical changes occurring during the mutual action of water, nitric oxide, and excess of oxygen, was never the subject of any special theory on my part. On the contrary, I accepted all the various equations given in the text-books, and showed that, no matter which be adopted, the ultimate result is the same in all cases, viz., nitric acid.—I am, &c.,

ERNEST T. CHAPMAN.

11, Sutherland Gardens, Harrow Road.
December 15, 1870.

ACTION OF ZINC ETHYL.

To the Editor of the Chemical News.

SIR,—In the last number of the CHEMICAL NEWS, I find a short note on the "Action of Zinc Ethyl Upon Phosphetted Hydrogen," by C. Schultz-Sellack. Allow me to state that, experimenting on the same subject several years ago, Dr. Drechsel and myself found that, contrary to Mr. S.-S.'s statement, zinc phosphine, $ZnHP$, or $Zn_2H_2P_2$, is readily formed, provided the ethereal solution of the zinc-ethyl be kept cold by a freezing mixture. The zinc phosphine is a perfectly white and amorphous powder, and is converted by the action of iodide of ethyl into Hofmann's well-known double compound of iodide of triethylphosphine and iodide of zinc. We never published the results of our investigation, and I cannot now give analytical data, but our analyses of the zinc phosphine, as well as of the ethylated double compound, agreed perfectly well with the formulæ.—I am, &c.,

B. FINKELSTEIN.

Hebburn, Gateshead-on-Tyne,
December 17, 1870.

MISCELLANEOUS.

Letts's Diaries for 1871.—We have received specimens of some of the diaries issued by this well-known firm. The Medical, Monthly, or Professional, and Appointment Diaries are exceedingly well arranged, and contain a large amount of valuable information. They will prove of great service to members of the various professions, &c.

Beer Brewed from Rice.—A. Metz.—It appears that the brewing of beer from rice has already assumed large proportions in some parts of Germany. The author has analysed a variety of this beer brewed at Weisenau, near Mayence, from a mixture of $\frac{1}{2}$ of malt and $\frac{1}{2}$ of rice. The beer thus produced is very clear, of a pale colour; the colorimetric test, according to M. Leyser's method, gave

as result that the colour of this beer was equal to that of a mixture of 100 c.c. of water and 1.2 c.c. of decimal normal iodine solution, while the colour of the Munich beers average from 3 to 3.5 and even 4.9 c.c. of the iodine solution alluded to in 100 c.c. of water. The taste of the rice beer is extremely pleasant, very mild; it foamed strongly yet retained its carbonic acid well. Specific gravity = 1.0238. The beer contained, in 100 parts—Alcohol, 3.65; sugar, 1.63; dextrin, 5.13; protein compounds, 0.37; mineral matter, including 0.0775 phosphoric acid, 0.22; loss, 0.01; total quantity of extract, 7.36 per cent, being made up, in 100 parts, of—Sugar, 22.15; dextrin, 69.70; protein compounds, 5.03; ash (including 1.05 of phosphoric acid), 2.99. In order to give a more correct view of the value of this rice beer, as compared with other beers, the author quotes the following average percentage results of analysis of twenty-one varieties of Bavarian beers recently analysed by Dr. C. Prandtl:—

	Munich beers.			
	Rice beer.	Average.	Maximum.	Minimum.
Alcohol ..	3.65	3.55	3.98	3.23
Total extract ..	7.36	6.17	6.61	5.42
Sugar ..	1.63	1.08	1.38	0.82

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Polytechnisches Journal von Dingler, first number for November, 1870.

This number contains the following original papers and essays relating to chemistry and allied sciences:—

Suggestions for the Construction of a New and Improved Bathometer.—Dr. H. Emsmann.—A bathometer is an instrument for sounding great depths at sea. The details of this paper cannot be well understood without the aid of the engravings which illustrate it.

Estimation of the Total Quantity of Carbon Contained in Iron.—Dr. Wittstein.—The author first states that the method suggested for the estimation of carbon in iron (crude cast-iron) by the late M. Berzelius, is the best and most simple. It consists in treating the iron with chloride of copper. The author's experiments with this method were conducted as follows:—1.25 grms. of coarsely pulverised iron were added to a liquid contained in a flask, and consisting of 50 grms. of water, 10 grms. of chloride of sodium, and 10 grms. of sulphate of copper. The iron was left in this solution for a couple of days. Ten grms. of hydrochloric acid, sp. gr. 1.13, were then added. The flask was next heated on a sand-bath. By this operation the hydrated oxide of iron and the finely divided metallic copper were dissolved, and after the liquid had been diluted with about twice its bulk of water, the carbonaceous matter was collected on a previously weighed filter, and dried at 100°. The quantity obtained weighed 0.007 grm., losing by ignition a quantity of 0.042 grm., which amounts to 3.36 per cent of carbon. The residue of the ignition was tested for the presence of iron and copper by dissolving it in nitro-hydrochloric acid (aqua regia). Both metals, to the amount of 1 centigram., were found to be present; the remaining silica was still found to contain a small quantity of carbon.

Testing of Graphite.—F. Stolba.—The author states that the ignition of graphite (previously well dried) may be readily performed in a platinum crucible, the lid of which is perforated with a hole of some 5 m.m. diameter. The lid is placed on the crucible in such a manner as to leave about one-fourth of its opening uncovered; the consequence of this arrangement is that a strong draught of air is caused in the crucible, whereby the combustion of the graphite is greatly accelerated and the combustion completed (supposing 0.5 grm. of substance to have been taken) in about four hours' time over a good Bunsen burner. The introduction of oxygen gas into the crucible is, according to the author, rather a disadvantage, as it often causes the fusion of the ash, and hence the withdrawal of carbonaceous particles from the oxidising action of the gas.

Progress Made in the Desilverising of Lead by Means of Zinc at the Royal Prussian Lead-Silver Smelting Works.—Dr. Wedding and Dr. Brinning.

Best Method of Extracting Indium from Zinc-blende (native Sulphuret of Zinc).—F. Stolba.—The author first pulverises the zinc-blende and next mixes that powder with about 10 per cent of its weight of burnt gypsum. This mass is made into a paste with water, and formed into round cakes of about three-quarters of an inch thickness, and from four to five inches diameter. Through these cakes holes are bored of about one-sixteenth inch diameter, and one and a-half inches apart. After drying, the cakes are ignited in a strong coal or coke fire; after thorough ignition the material is ground to powder, and treated with hydrochloric or sulphuric acid, and the indium precipitated from the acid solution, while boiling in a copper kettle, by means of zinc.

Testing for Cæsium as Double Chloride of Tin and Cæsium.—F. Stolba.—This paper contains an exhaustive account of an analysis of lepidolite from Rozna (Austria). The chief point of interest in reference to the preparation of the double salt alluded to, is that ammonia should be rigorously excluded from the materials, because the ammonium stannochloride is as insoluble in concentrated hydrochloric acid as the cæsium stannochloride.

Use of Peat as Fuel Mixed with Coals.—Dr. Dingler.—This Paper treats on the best plan of utilising peat mixed with coal for the purposes of steam-boiler and other furnaces.

Reduction of Tellurous Oxide by Grape Sugar.—F. Stolba.—The author, states that when tellurous oxide, dissolved in excess of potassa or soda solution, is heated along with grape sugar, the result is the precipitation of metallic tellurium in finely divided state.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 14, 1870.

Nitration of β Naphthol.—O. Wallach and H. Wichelhaus.—In the introduction to this paper the authors briefly refer to a method of nitration invented by the late Dr. Bolley, and applicable to such bodies as resist the ordinary processes used for this purpose. This new process has been applied by the authors to the nitration of β naphthol previously obtained free from any α naphthol, the result being the formation of binotro-naphthol, $C_{10}H_7(NO_2)_2(OH)\beta$. This substance crystallises in small needle-shaped crystals, fuses at 195° , is very difficultly soluble in water even if boiling, but more readily so in alcohol, and very readily in ether and chloroform; these solutions exhibit an intense yellow colour. The β nitro-naphthol does not form salts so readily as the α compound analogous to it.

Acetyl Derivatives of Ammonia.—H. Wichelhaus.—The first portion of this paper contains a lengthy series of complicated formulæ, exhibited for the purpose of showing how triacetamide might be formed. The author next states that he has succeeded in obtaining that body by heating together acetonitrile and acetic acid to a temperature of 200° . The substance thus prepared is a solid, crystalline form, fusing at 79° . The larger portion of this paper is devoted to theoretical discussions on reactions which might be called into play. Triacetamide is neutral in its behaviour with test paper while in solution; diacetamide tinges blue litmus paper red.

Preliminary Notice.—C. Huber.—The author states that the body obtained by him some three years ago by the action of bichromate of potassa and sulphuric acid upon nicotine, viz., the acid $C_8H_7NO_3$, is not, as has been formerly announced by him, an amido-acid, but pyridine carbonic acid.

On Nitro-chlorophenol.—T. Petersen.—This extensive essay, illustrated by several crystallographical diagrams, is divided into the following sections:—Mononitro-monochlorophenol, dinitro-monochlorophenol, trichloronitrophenol, and trichlorodinitrophenol.

On Yttrocerite.—Dr. C. Rammelsberg.—After briefly referring to the labours of the late Dr. Berzelius on this mineral, which occurs near Fahlun (Sweden), the author states that, having recently analysed this mineral, he found it to consist of, in 100 parts—Lime, 47.27; oxide of cerium, 9.35; yttria, 14.87; loss by ignition, 2.52; the remainder being fluorine. The formula of this substance is—

The specific gravity of this mineral is 3.363.

On Sulphocarbonylchloride and on a New Chlorosulphide of Carbon, the Perchloride of Methylmercaptan.—B. Rathke.—The introduction to this essay contains an account of the researches made by Dr. Kolbe, some twenty-five years ago, on this subject. The paper then treats at great length on a series of compounds obtained by submitting to fractional distillation the various substances formed by the action of chlorine upon sulphide of carbon. Four different products of fractional distillation were obtained, viz., (a) a liquid boiling below 80° , which contains, besides unaltered sulphide of carbon, also chloride of carbon and sulphocarbonylchloride, which imparts to this fluid a reddish yellow colour, and a very suffocating odour; this last-named substance could not be obtained in a free state by fractional distillation; (b) at from 80° to 140° a mixture of the substance alluded to under (a), and of another body, came over; (c) at from 140° to 150° large quantities of a yellowish oily liquid was obtained; while, lastly (d), there remained in the retort trichloromethyl sulphocarbonylchloride mixed with the oily body just specified. By carefully instituted distillation the author obtained a liquid boiling at between 146° and 147° , of a golden yellow colour, emitting vapours of hydrochloric acid by exposure to moist air, and depositing sulphur at the same time; this body is perchloride of methyl mercaptan, $CSCl_3 = CCl_3.SCl$. The author gives a long description of the various reactions which this body exhibits with different reagents.

The Law of Avogadro.—A. Naumann.

Journal für Praktische Chemie, No. 16, 1870.

Concluding Portion of the Essay on the Influence of Temperature upon the Molecular Rotatory Power of some Circularly-Polarising Bodies.—Dr. C. Tuschschmid.—This memoir is illustrated with six lithographic plates.

Decomposition of Sulphide of Carbon by Heat.—W. Stein.—The author relates a series of experiments made with perfectly pure sulphide of carbon. His results show that sulphide of carbon is not decomposed by a very high temperature if charcoal is simultaneously present; it is therefore necessary to keep the retorts plentifully supplied with either charcoal or coke.

Ether of Sulphon-Acids.—L. Carius.—In the introduction to this essay, the labours of various authors on this subject are referred to, and ethyl-sulphon-chloride is described. The further portions of this paper treat on:—Ethyl-sulphon-acid ether.—A colourless fluid, insoluble in water, which slowly decomposes it, even at the ordinary temperature of the air; it boils at 207.5° ; $S(C_2H_5)_2O_3$; sp. gr., 1.1508. This substance combines with ammonium, forming ethyl-sulphon-acid-ethyl-ammonium, $SC_2H_5(NH_2C_2H_5)O_3$. Ethyl-sulphon-acid-methyl.—A colourless liquid, also decomposed, when in contact with water; boils at about 200° ; formula, $S(C_2H_5CH_3)O_3$. Ethyl-sulphon-acid-amyl.—The author states that he did not prepare this compound; but that a substance formerly prepared by him, and then named sulphurous acid-ethyl-amyl, is, in reality, ethyl-sulphon-acid-amyl.

Oxamyl-Sulphon Acid (Amyl-Isethionic Acid).—F. A. Falk.—This memoir treats on amylen-chlorhydrine and products derived therefrom, among which is oxamyl-sulphon-acid, $C_5H_{10}(HO).SO_2.HO$, and the salts it yields with sodium, ammonium, calcium, barium, copper, lead, and silver.

Isethionic Acid and the Homologous Substances thereof.—L. Carius.—A critical review of a work lately published in Germany under the above title, by Dr. E. Schwarz.

Specific Gravity and Expansion of the Ethyl-Sulphon-Acid Ether.—L. Carius.—The first portion of a lengthy memoir illustrated with woodcuts, and containing a series of tabulated forms exhibiting the results of experiments and analysis.

NOTES AND QUERIES.

Manufacture of Kelp.—Can any reader give me the name of any book on kelp manufacture, and the manufacture of bromine and iodine? I have Richardson and Watts.—A STUDENT.

Orange-Lead.—(Reply to J. Dodd).—You will find every information on the subject in Gentile's "Lehrbuch der Farben Fabrikation," a work which you can inspect at the library of the Commissioners of Patents.

Separation of Tarry Matter from Gas-Water.—(Reply to "Gas Engineer").—Perhaps you might apply filtration of the liquid through a layer of previously well washed pebbles placed in layers of varying thickness and the largest size on the top.

Separation of Tarry Matter from Gas-Water.—The simplest way to separate light tar from gas water is to bring it intimately in contact with heavy tar, and afterwards let settle for a few hours. This will remove the mechanically mixed tar, but not that which is chemically dissolved.—JAMES DONADD.

Aniline Colours.—Can any of your readers inform me of the best and cheapest method for precipitating the aniline colours in the form of lakes for the use of paper stainers. According to Perkin's lecture, in the CHEMICAL NEWS, alumina is used along with tannin. I wish to know in what state the alumina is added, also the tannin, and if there are no other earthy substances that will answer the purpose as well as alumina.—STAINER.

MEETINGS FOR THE WEEK.

TUESDAY, THURSDAY, and SATURDAY, at 3 p.m. each day. Royal Institution. Juvenile Lectures on "Burning, and Unburning." By Professor Odling.

TO CORRESPONDENTS.

* * Our Publisher requests us to remind Subscribers that, if their Subscriptions for the ensuing year are sent to him in advance, the amount for one year will be 18s., no postage being charged; but if accounts are sent from the Office, the subscription will be £1.

China.—Richardson and Watts' "Chemical Technology," will give you full information on the subject. You will also find particulars in "Traité des Matières Colorantes," &c., par M. P. Schützenberger; vol. i., p. 365.

W. R.—We have never seen the statement you allude to. **S. E. Phillips.**—The formula was an exact copy of the original. **Robinson, Brothers.**—(1). If you write to Messrs. Gehe and Co., Dresden, they will probably send you their lists. (2). Messrs. Trübner have published a dictionary which would meet your requirements.

G. Hay.—This correspondent writes to say that in the tenth line of his letter of last week, he used the words "mixed acids" instead of "dilute acid."

THE CHEMICAL NEWS.

VOL. XXII. No. 579.

ON A POSSIBLE SOURCE OF ERROR IN PENNY'S PROCESS FOR THE VOLUMETRIC ESTIMATION OF IRON.

By J. SPEAR PARKER.

HAVING occasion to determine the excess of oxygen in an oxide of manganese combined with a considerable amount of cupric oxide, I endeavoured to do so by dissolving a portion in the solution of a known quantity of iron in hydrochloric acid, afterwards attempting to determine the iron remaining in the state of ferrous chloride by titration with a standard solution of potassic dichromate.

On approaching the termination of the reaction I was surprised to observe the well-known brown colour of cupric ferrocyanide when tested as usual by addition to drops of a weak solution of potassic ferricyanide, thus rendering it impossible to obtain an accurate estimation.

This reaction was evidently owing to the formation of ferrocyanide by the small quantity of ferrous salt present, and consequent precipitation of the copper.

This proved to be the case, for, on dissolving some cupric sulphate, together with about one-fourth its weight of ferrous sulphate, and then adding a solution of potassic ferricyanide, the cupric ferrocyanide was precipitated as before. Its identity was readily proved, for on treating the washed precipitate with potassic hydrate, immediate decomposition ensued, the blue cupric hydrate being produced, altering to the black oxide on boiling. The filtrate was of a pale yellow tint, and after acidification gave, with ferric chloride, a Prussian blue, with ferrous sulphate, a bluish white precipitate. The reaction takes place both in neutral and acid solutions, probably according to the following equation:—

When the amount of copper is small, this brown colouration would not be distinguished from that always produced by ferric salt, and might therefore escape the notice of the analyst, were it not that previous to this the mixture of blue and brown, caused by the presence of a slight excess of ferrous salt, gives a grey or blackish tint, which would at once arouse suspicion. This source of error would seldom occur in practice, being rendered still less probable by the fact that reduction with metallic zinc, which frequently precedes titration, would remove all copper from the solution. Nevertheless, I thought it advisable to place the reaction on record, as I am not aware that it has been previously observed.

ON APPARENT PARALLELS TO REGELATION.

By CHARLES W. VINCENT.

THE re-solidification of broken ice at temperatures above the freezing point has its parallel phenomena under like circumstances in the cases of many other substances. Some of these are well-known, and at times exceedingly troublesome to workmen in certain manufacturing businesses where rapid liquefaction is a desideratum, but have not, I believe, been noticed in any scientific journal. I note a few instances from my own observation.

(1). *Rosin*.—Good black rosin, free from turpentine, when subjected to pressure in a mould, or otherwise, at ordinary temperatures, becomes completely pulverised, its particles showing no cohesive power whatever (the appara-

tus used was similar to that adopted by Dr. Tyndall for regelation of melting ice).

(2). When the temperature of the mould is raised considerably above the melting-point of rosin, on pressure being applied, a different result ensues; the mass becomes at once solid to the core, the outside alone showing signs of liquefaction.

(3). When rosin has to be melted for manufacturing purposes, if even for a few minutes only the workman neglects to stir, the whole mass becomes completely solidified, and the liquefaction is only carried on at the exterior of the mass, which, when pounded by his stirrer, breaks up without giving the slightest preference to the previous lines of fracture.

(4). The phenomenon is best seen when the temperature of the pan is sufficiently high to melt the outside of the rosin before it has had time to be warmed through.

(5). Pitch, at melting temperatures, gives the same result as rosin, but becomes viscid so much sooner, that though coagulation is readily affected, yet the perfect junction of the broken pieces into a solid mass is not so readily obtainable.

(6). The gums used in the manufacture of varnishes, such as dammar, copal, anime, shellac, &c., give similar results. Whilst being run down at high temperatures, they settle together and cohere (if their surfaces be clean) without the possibility of again separating them in the same places; and this while the exterior of the mass is rapidly melting into liquid of almost the fluidity of oil.

(7). If the temperature of the pan in which any of these viscid substances is being melted be advanced by slow degrees to the point of their real fluidity, the viscosity interferes with the perfect manifestation of the previous results noted—but the aggregating force is still shown—for the separate pieces of rosin, gum, or such like substance, take the same degree of viscosity, and combine into one homogeneous mass, whilst the more rapid melting goes on on the outside of the whole.

(8). From these instances I am inclined to infer that the disintegration caused by liquefaction of one part of these bodies causes them to exert a greater power of aggregation in the parts less exposed to heat.

Royal Institution, December 28, 1870.

ON THE EXAMINATION OF THE BESSEMER FLAME WITH COLOURED GLASSES AND WITH THE SPECTROSCOPE.*

By J. M. SILLIMAN, M.E.,

Adj. Professor of Metallurgy, Lafayette College, Easton, Pa.

I. Examination with Coloured Glasses.

In the Bessemer process, the progress of the decarbonisation is determined chiefly by the appearance of the smoke, flame, and sparks which are emitted from the apparatus. Owing to the rapidity with which the reactions take place, it is highly important to catch the exact moment when the blast should be turned off. This is indicated by the colour and brightness of the stream of gas issuing from the converter, and by this the moment of total decarbonisation can generally be accurately determined by the naked eye. When, however, pig-iron of certain qualities is used (manganiferous iron, for example) this determination is very difficult; even those who have had much experience make frequent mistakes and find it impossible to produce the same quality of steel at every blow.

In order to intensify these flame-indications, use has been made of the spectroscope, and also of various combinations of coloured glasses. The former was first

* Read at the Troy Meeting of the American Association for the Advancement of Science.

attempted by Dr. Roscoe, and the latter by Mr. Rowan at the Atlas Works.

Mr. Rowan experimented with a great variety of coloured glasses, and obtained the best results by using three glasses, two of ultramarine-blue and one of dark yellow. This little instrument, or chromopyrometer, as he terms it, is now in daily use at the Atlas Works, its indications being so marked and unmistakable as to render its use safe in the most inexperienced hands.

The following experiments were made at the Bessemer Steel Works of John A. Griswold and Co., in Troy, while pursuing the chemical course in the Winslow Laboratory of the Rensselaer Polytechnic Institute. In my observations on the flame I made use of the spectroscopic, and also of a combination of coloured glasses. This combination consisted of two light yellow glasses and a blue one, through which the sunlight appeared of a deep purplish-blue tint; and as it differed slightly from Rowan's, it gave somewhat different results.

In order to reproduce the appearance of the flame at the different stages of the process, I prepared a plate consisting of about a hundred varieties of colours and tints, all of which were numbered and thus referred to a table which indicated their composition. They were also arranged to be seen with either a light or dark background. The use of this plate was of necessity limited to daylight, but the illustration and description are given as occurring at night in order to show its illuminating power.

At the beginning of the process that which issues from the converter does not appear to be a true flame, but only an illumined stream of gas carrying with it innumerable red-hot pellets of iron. This gas has scarcely any illuminating power, extends but for a short distance from the mouth of the converter, and is sometimes sheathed with a whitish smoke. Seen through the glasses, the flame and sparks have a deep crimson colour, the converter is invisible, and at the base of the flame is a crimson band which continues throughout the process.

As the reaction continues, this stream of gas grows brighter and more elongated, and, after a few minutes a small pointed whitish flame appears, which suddenly increases in size. At this instant the blast-pressure falls from 20 to 18 pounds.

When viewed through the glasses, the upper part of the converter comes dimly into view, and the flame and pellets of iron appear of a lighter colour, while the fragments of slag which begin to be thrown out are of a deep red. This difference in shade between the iron and slag thrown out is, probably, entirely owing to the lower temperature of the latter, for the reason that while the iron is discharged from the metallic bath the slag is washed up on the sides of the converter, and can be seen clinging around its mouth in a spongy mass until detached and thrown out by the blast. The greater porosity of the slag and its consequent more rapid cooling would also cause a difference of temperature.

In the second period the discharge of slag increases, and the flame is very bright and illuminating, with occasional dark streaks. Through the glasses at the beginning of this period the flame is of an ashy blue colour with streaks and flashes of crimson, the edges being sometimes of a purplish hue. At this point surrounding objects are illuminated, and the converter becomes distinctly visible. A wreath of crimson is seen surrounding the flame where it strikes the chimney. By the middle of this period the crimson almost entirely disappears from the body of the flame, leaving only a slight cone at its base, and a border of greenish hue makes its appearance, and gradually grows more decided. Streaks of a dark blue colour are also seen in the body of the flame.

The beginning of the third period is scarcely indicated to the naked eye, though the flame becomes somewhat weakened, and after a few minutes shows dark streaks running through it. Through the glasses at the commencement of this period the rose-coloured cone begins to expand and deepen, the greenish sheath is more decided,

while streaks of dark and green are visible. After a few minutes the change becomes very rapid, a few seconds only being required to reduce the flame from rose-colour to the deep crimson non-illuminating gas, as at first, and again the converter is lost to view, by which time the blast should have been turned off.

The gradual fading of the crimson from the beginning of the blow and its deepening at the termination of the process, as well as the crimson band at the base of the flame and the wreath of crimson surrounding the flame at the chimney, tend to confirm Mr. Rowan's views, which are, that the different shades of crimson are due to changes of temperature. The stream of gas which comes from the mouth of the converter at the beginning of the process, being illumined from within, derives its colour from the metallic bath, the temperature of which, owing to the combustion of silicon, increases more rapidly during this period than at any other.

The crimson band at the base of the flame, and the wreath of crimson at the chimney might also be accounted for by this theory. The flame rushing from the mouth of the converter has a tendency to create a vacuum at its base around the converter's edge, and thus to cause a wreath of flame to pass over this surface, and by consequent cooling produce the crimson band. The wreath of crimson at the chimney may be also due to the cooling of the flame consequent upon deflection.

It is true we have a seeming contradiction to this theory in the rose-coloured cone extending from the base at the centre, which we would naturally consider the hottest part of the flame; but, as in the flame of the Bunsen burner, the hottest part is in its outer sheath, the conditions of combustion in both being similar, it is probable that that part of the flame occupied by the cone is at a lower temperature than that surrounding it.

The green streaks in the flame are most intense when the manganese spectrum is brightest; and as the colour of the flame when the spiegeleisen is added is also green, we are led to suppose them due to the presence of manganese.

On two occasions simultaneous observations were made with the spectroscopic and the coloured glasses; but with the exception of that just mentioned, and the changes at the commencement and termination of the blow, no striking coincidence was noticed.

(To be continued).

ON THE EXTRACTION OF THE POISONOUS PRINCIPLE OF THE TUTU PLANT (CORIARIA RUSCIFOLIA).

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

A GREAT many experiments have, from time to time, been made upon the Tutu plant, with the object of extracting the formidable poison known by sad experience to exist therein; but, as is well known, these attempts have been always unsuccessful, and have, besides, completely failed to discover anything at all definite as to the chemical or physical character of the poison.

Among these experiments is a series I made while connected with the Geological Survey Department of Otago, a notice of which appeared in the "Juror's Report for the New Zealand Exhibition of 1865," the only result, however, being to prepare the way for future inquiry, which was promised at the time.

The Tutu plant does not grow in the neighbourhood of Wellington in any quantity, hence I have been greatly delayed in fulfilling my promise, much against my will; but recently a large quantity of the seed of this plant has been kindly presented to the Survey, for this particular purpose, by Mr. H. H. Travers, and upon this I at once commenced operations.

The plan I adopted was to separate, as well as I could, all the more immediate proximate constituents of the seed (in which the poison is known to exist), and to test each likely one by itself, in its effects upon the animal economy.

First, I extracted a portion of the finely-ground seed with cold water, and another portion with weakly acidified water, and treated them separately by a new process, now much in vogue, for the separation of alkaloids (Rogers and Girwood), all the evaporations being conducted at a temperature not exceeding 90° F.

The residuum from these processes was very small, and gave no indications of the presence of alkaloids to the proper tests; it consisted almost wholly of gummy matters.

The result seemed to dispose of all that was soluble in water or weak acids, and, to a certain extent, impugned the correctness of the general idea that this poison is of the nature of an alkaloid.

The part of the seed insoluble in these reagents was next examined.

Alcohol was passed through this repeatedly, and the extract evaporated, when a large quantity of a greenish-red coloured substance discovered itself. This, treated with ether, separated into two parts, one a green-coloured oil, soluble therein, the other a resinous substance quite insoluble in this menstruum.

The resinoid substance was reserved for after-examination, and the oil at once tested in regard to its effects on the animal economy.

For this purpose I administered about five minims of it to a full-grown cat, after a twelve-hours' fast; the oil acted as an emetic in a short time, and the greater portion of it was vomited. In half-an-hour, however, the animal showed signs of uneasiness, and convulsive twitches of the ears and eyes, together with a forward jerking of the head, took place, also much frothing of the mouth, culminating in a convulsive fit, in about one hour after the dose was administered. After a little while this fit passed off, only the twitches and forward jerkings continuing; but a second very severe fit, of short duration, occurred in about one hour afterwards, after which the cat gradually rallied. These symptoms agreed generally with those exhibited by cattle and sheep, when poisoned by this plant.

Although I have made but one experiment, I think it will be allowed that the result of this has fairly proved that the poison of the seed, and so, by a very proper inference, the poison of the plant generally, since I find an oily substance throughout it, exists in this oil, if it is not the oil itself. It therefore now only remains to be ascertained whether this oil is a single proximate substance or a mixture or compound of such, and if the latter, which is, or which are, the active ones concerned in the production of these phenomena I have described. Unfortunately, I had not sufficient of the oil to allow me to test this properly, but I am in hopes of having it shortly, as I have been promised a large quantity of these seeds from Taranaki.

The following are the characteristics of this oil, as ascertained up to the present time.

Somewhat viscid at common temperature, but flowing freely at a little above this; colour, pale-green; reaction, acid; taste, bland; burns away readily with much flame; scarcely volatile without decomposition; soluble in ether, alcohol, chloroform, and strong acetic acid; insoluble in hydrochloric or nitric acid; also insoluble in water; does not dry when long exposed to the air.

When boiled with solutions of the caustic alkalies there is much frothing, but only a portion of the oil dissolves, even when the boiling is continued for many hours; the portion dissolved was found to be saponified. The whole of the oil is, however, soluble in a cold alcoholic solution of potash, without yielding a precipitate when admixed with water; hence it is probable that all the acid portion of the oil is really saponifiable, that which was

unsaponifiable, in the first instance, being a product of the metamorphosis of a portion of the normal oil by the process employed.

When the oil is heated to the decomposing point, a substance is given off having the pungent odour of acrolein, a substance characteristic of the presence of glycerine, or oxide of lypyle, the base of common fatty bodies.

Heated with caustic alkalies, either in the wet or the dry way, there are no alkaline vapours evolved, but in the latter case an odorous oil forms, probably cenanthylic acid.

From the reaction of this oil, here described, it evidently belongs to the series of non-drying fixed oils; in its solubility in alcohol or acetic acid it bears a remarkable resemblance to castor-oil, the only other fixed oil which I find to be wholly soluble in acetic acid. Now, castor-oil, it will be remembered, is a very peculiar oil. It does not contain any of the acids of the common oils or fats, but, in place of them, two very singular acids, quite peculiar, I believe, to this variety of oil; hence I conceive that the acid part of this oil of Tutu to be also quite distinct from the ordinary fatty acids; to be in all probability, peculiar to it; and to one or more of these acids I should ascribe the poisonous effects of the oil.

If further experiments should confirm the correctness of the views here stated, this case will, I conceive, become invested with an interest beyond that immediately under our notice, since it will offer another instance in which a non-nitrogenous oily principle is proved to affect the system like a neurotic poison, this class of poisons being almost always alkaloids, or at least nitrogenous substances.

Now it will be remembered there are several poisonous plants in Europe, which have, hitherto, refused to yield any pure poisonous principle to chemical processes, but then these processes have been, as a general rule, I believe, especially for the detection of alkaloids. With this case to point, therefore, it does seem in the highest degree probable that, in some of these cases, at least, the poisonous effects may be due to a non-nitrogenous oil, not yet isolated or examined. In view of this I have recommended the subject for examination to a friend of mine residing in England, so that I expect in a few months to hear something more of this, or else to have selections of seeds, &c., from the plants I have named in my letter, so that I can inquire into this subject myself.

With regard to antidotes for administration to animals, &c., poisoned with the Tutu plant, I should be inclined to think that, in addition to emetics and purgatives, very dilute acids would be beneficial, since, by preventing saponification of the oil, they would tend to keep it insoluble, and therefore inert.

As being somewhat related to the subject, I may state that the seed of the Karaka tree (*Corynocarpus laevigata*), which is also of a poisonous nature, has refused, in a similar manner, to yield any alkaloid to my processes, but it gives up an oil to alcohol, which resembles the above in some of its reactions. It seems to exercise a specific effect upon the animal economy when administered in small doses, inducing at first great uneasiness, and afterwards restless, unwilling sleep, with sudden starting. Unfortunately I had not sufficient of it to get any decisive results.

This oil is also soluble in alcohol, acetic acid, ether, and in hydrochloric acid.

It is very bitter, and feebly soluble in water.

In one important respect it differs from the oil of Tutu. It evolves ammonia when boiled with potash, thus, in regard to its composition, allying itself to the alkaloids, though in its reactions apparently distinct.

* Since this paper was read, I learn from the CHEMICAL NEWS (vol. xx. p. 701) that M. Van Anken has discovered the poisonous principle of the *Crotia virosa* to be an essential oil, of formula $C_{10}H_{16}$, but "could not find any alkaloid in this plant at all." This was one of the plants especially selected for examination in the communication alluded to.

ON FERMENTATION.*

By Professor A. W. WILLIAMSON, F.R.S.

(Continued from page 315.)

In the composition of alcoholic ferments there are several substances of which we know very little at present, I am sorry to say, but the want of this knowledge is so great that I have no doubt it will be soon supplied. Certainly this is a most important field for the investigation of naturalists who possess an accurate knowledge of chemical manipulation; I mean the simplest and lowest organisms, whose functions are of such importance in these changes, certainly claim much careful investigation. But some of the things which we do know about the yeast cells I must now state, with relation to the facts and ideas which we have just had before us. In the first place, with regard to their growth; it is very common, in the process of brewing, to feed the yeast cells with a substance which is formed in the germination of barley. When barley is left in a moist state, at a suitable temperature, it begins to sprout, and during that process there is a change in two of its constituents, which I showed you the other day. One is gluten, a body containing nitrogen, which I compared, for the sake of convenience, to muscular fibre, being in reality very closely allied thereto in chemical composition, and during the germination of the seed this substance passes over into some product or products—I had better speak quite generally—known by the name of diastase. In the yeast cells there is a substance very nearly resembling in composition that of gluten, and it cannot be doubted that this gluten, or albuminous body as it is frequently called, is capable of undergoing a similar transformation into diastase, and of all foods the yeast cell enjoys most those which contain diastase. I have a good many yeast cells growing in a suitably heated chamber, and those which seem to thrive most are some which were put into an infusion of malt, to which sugar was added. It is common, in the process of fermentation, to put in yeast in tolerable quantity, but the extent to which it grows depends upon the time for which it is left in contact in the material. I am told that the common proportion is about one-twentieth of the quantity of yeast required. For instance, if 20 lbs. of yeast are wanted to effect a given fermentation, you put into the liquid which has been fermented 1 lb. of yeast calculated in the dry state, and give it this diastase to feed upon. At the same time, there is sugar present in the liquid, and during the process of fermentation this pound weight of yeast increases more and more, by a process of true germination and growth. Professor Mitcherlich actually saw, under the microscope, some little cells, of yeast sprout, and put out, from the side of the parent cell, small cells which gradually increased in size. The actual process, however, has not been seen by many observers. And not only does the yeast cell in that way feed upon these albuminous bodies, which are grouped together by the name of diastase, but it also takes part of the sugar; and these are the two prominent facts which we know with regard to its food—that it feeds upon substances of those two classes; sugar, which contains no nitrogen, and also nitrogenous substances, which are formed by the partial breaking-up of the gluten. On the other hand, its decomposition—I mean during its life—I am not speaking of any decomposition which its materials may undergo if it is killed—gives off alcohol, carbonic acid, succinic acid, and glycerine; in fact, the four chief products of ordinary alcoholic fermentation, which I enumerated to you the other day. And while these products are being given off, there is at the same time a considerable quantity of nitrogenous substances being given off. The albuminous matter in the yeast cells is undergoing decomposition, and is giving off nitrogenous substances. There is not any well-authenticated case of the yeast cell forming,

during its active functions, products of complete breaking-up or putrefactive decomposition; all the products which we know best are substances of considerable complexity—less complex than the materials of the plant, but of great complexity; and, accordingly, the notion which Liebig had that the yeast-cell is active in the proportion as its materials are undergoing complete analyses or breakings-up, and forming ammonia and carbonic acid, is not now entertained by that distinguished philosopher.

Some time ago, an exceedingly important experiment was made by M. Pasteur, with a view of testing the vital functions of the yeast cells in a definite way. The statements which I have made to you contain a good many terms which are exceedingly general, as, for instance, the allusions to diastase. We really do not know what that is. We know about what sort of a thing it is made from, but not definitely. And the same with the nitrogenous products which are given off by the yeast cells; we know something about them, but only a little. Pasteur put into a solution of sugar, in which some yeast particles were present, some ammonia combined with an acid, and at the same time he put some of the ashes of other yeast cells. He took a certain quantity of yeast and burnt it, so as to remove by oxidation the carbon, hydrogen, and nitrogen of the substance, and the earth substances which remained, which are essential to the formation of a new yeast cell, he put into some fermenting liquid, together with some salt of ammonia. When he did that, he really was treating the yeast cells very much in the same way as a good farmer treats the wheat plant. If you want a wheat plant to increase rapidly, you must, in the first place, take care to supply to it all that the wheat plant takes up in the shape of mineral matter from the soil, and the best way to find that out is to burn some wheat and see what is left. Then you must supply plenty of ammonia, and the more ammonia you supply up to a certain extent, the more rapidly does the wheat grow, by building up various simple substances into the complex substance, gluten, which I was speaking of just now. Pasteur put into such a mixture a few little cells of the yeast, and they did not thrive. They did transform some sugar into alcohol and carbonic acid, but they evidently were not at home, and at the end of a certain time, I forget how long, he found there was actually a smaller weight of yeast present than he had put in. That was a very different result from what happens when nitrogen is supplied to the yeast plant in the form which I mentioned just now as the usual one; and I think the fact is most instructive, and serves to show us what kind of a being the yeast cell really is—I mean whether it should be classed among animal or vegetable beings. I need hardly say that absolute distinctions amongst beings which we find in nature are out of the question; we do not generally get any absolute line of demarcation, for one class flows over into the other; but still the ideas which serve us to classify organic and other beings are exceedingly important, and in a case like this it is certainly of considerable interest to have some leading idea, by which one may see whether there is a reason for placing these beings amongst vegetable or animal organisms, and we cannot help giving special weight in that respect to the kind of process which the respective classes of beings carry out in their organisms. Plants build up complex substances from simple. All the most complex substances that we can get are made in the organisms of plants. They may have been taken over by animals from plants, but they are formed in the main by plants. And the chief chemical activity of animals is precisely opposite; they take those complex substances and break them down, by means of their vital functions, to the simple products which are exhaled and given off in the processes of animal life. Therefore, the question whether the process which the yeast carries on is a synthetical process—a building up, or whether it is in the main an analytical process, is certainly one of the most important which can guide us. Now, I think what I have said must appear to you all most conclusive in that

* The Cantor Lectures. Delivered before the Society of Arts.

respect—that what we know best regarding the nature of the yeast cells, the food which we know they take in large quantities, and upon which they live, is certainly exceedingly complex, and what the yeast cells take up in preference is certainly sugar, and the very complex nitrogenous substances which are at present in solution in the malt, and the products which they give off are exceedingly simple in comparison. Their functions are in the main (those which we know best, at any rate) analogous to those which take place in animal organisms, and are most remote from those which take place in vegetable organisms.

In a paper which he has recently written on the subject of fermentation, Liebig has drawn attention, amongst other things, to the circumstance that the common alcoholic ferment can be made to eat tartaric acid. If you were to neutralise a solution of some of these crystals in water, and put with the solution some yeast cells, at the same time supplying some nitrogenous material, the yeast plants would grow, and transform that into other substances. In the same way, if you were to put in some of this malic acid (which got its name from the circumstance that it is present in sour apples), the yeast cells would also transform that; and the same in other cases. One of the most remarkable decompositions is that of nitric acid, which, by the action of the yeast cells, is deprived of some of its oxygen, and converted into nitrous acid, so that it would appear that the plant can actually assimilate or eat the nitrates, forming these simpler derivatives from them.

There is one case which I should like to show you, of an inorganic action, one in which there is no vital process concerned, but it bears a sort of general resemblance to what I conceive to be the principle of those which I have been speaking of. I have here a piece of platinum in a peculiar state, which is well described by the term "spongy." If I hold it in the flame of common coal-gas mixed with air, from a Bunsen burner, the spongy platinum eats the air or the oxygen contained in it and the gas. The word "eat" is not really so inappropriate as it may seem. If I were to put this spongy platinum into oxygen, I should find that it would combine a quantity of oxygen into its substance, and make it part of itself, and the same with regard to the coal-gas. So that here you see, from the heat which was given off, the substance is really effecting a chemical change upon the materials which it absorbs, and it effects that change in its own substance. It is admitted that, in some way or other, the yeast organisms—I will not again call them plants—actually assimilate and make part of themselves, the sugar, or tartaric acid, or whatever it may be which they decompose; but they do not give off that substance which they have eaten in the same form. They give off its elements, after they have undergone a re-arrangement in other ways. At our next meeting I propose to bring before you some different considerations regarding the vital functions of these organisms, and some points which bear upon questions of sanitary importance.

(To be continued).

ON THE ESTIMATION OF GRAPHITE IN CARBURETTED IRON.

By M. BOUSSINGAULT.

CAST-IRON and certain kinds of steel contain carbon in two different states, viz.; (1) combined with the iron and therefore not visible in separate particles; (2) disseminated through the metal either in the form of an amorphous black powder, or in that of brilliant crystalline laminae, constituting the graphite of the metallurgists. There is some ground for the belief that while cast-iron is in the molten state all the carbon it contains is then

chemically combined therewith and dissolved, as it were, in the iron, but, on cooling, it appears as if a portion of that carbon is set free. Black granular cast-iron (granular on the fracture) exhibits a number of lamellæ of graphite. This is less prominent in grey cast-iron, and it is not visible in white cast-iron, neither in the kind called spiegeleisen, in both of these it can only be detected by careful analysis. When carburetted iron is dissolved in chlorhydric acid, the state of the carbon is at once shown. The free carbon or graphite remains along with the other insoluble matters. When iron does not contain graphite, but only combined carbon, there is no carbonaceous residue left on the iron being dissolved in hydrochloric acid, but in that case the carbon is eliminated during the solution of the iron in acid, communicating at the same time to the hydrogen gas evolved a peculiar and characteristic foetid odour. Steel which contains neither graphite nor scoræ (siliceous and other matters derived from the flux) dissolves in the acid without leaving a residue. When a grey cast iron is dissolved in hydrochloric acid, it will evolve a foetid hydrogen, but leave simultaneously a carbonaceous residue, because such kind of iron contains carbon in the two conditions of combination, as well as mixture.

In the year 1799 Proust first called attention to the oily matter developed during the action of an acid upon black cast-iron. He discovered that a portion of this oil was carried off by the hydrogen gas, communicating to it an alliaceous odour, while another portion remained combined with the carbonaceous insoluble residue, from which it might be extracted by means of alcohol. When cast-iron is acted upon by hydrochloric acid the graphite contained in the iron is separated, while the combined carbon is eliminated during the reaction along with the hydrogen gas. The graphite left as a residue insoluble in acid can be quantitatively estimated by burning it in oxygen gas, its weight being determined by the loss of weight of the insoluble residue, provided the iron were fully dissolved, and even if some portion of that metal has remained undissolved, it is possible to estimate the quantity of graphite by this method, by so arranging the apparatus as to admit of weighing the quantity of carbonic acid obtained. When we have to deal with a mixture of graphite and carbon of combination, such as is, for instance, obtained by the action of bichloride of mercury upon grey cast-iron, the quantitative estimation of the two species of carbon is effected by first heating the mixture to a temperature not exceeding dull red heat, and with contact of air, whereby the combined carbon burns off, and the graphite being left is next consumed in a current of oxygen aided by a white heat; there remains after that the silicate due to the silicium of the iron. This silica sometimes contains slag. After every combustion it is best to heat the residue in a current of hydrogen gas, in order to reduce again to the metallic state any iron which might have been left among the carbonaceous matters. I have especially adopted this method of estimation of graphite and combined carbon in iron in order to save the trouble of recurring to the long and tedious process of organic elementary analysis. Although the estimation of graphite and combined carbon in iron by the method founded upon the different combustibility gives very correct results, I have deemed it necessary to compare these results with those obtained by the previous separation of graphite followed by its combustion, while simultaneously I could study the nature of the residue left by a graphitic iron when dissolved in an acid.

(1) *Doughly Cemented Steel*.—1.5 grms. treated by the bichloride of mercury yielded:—

	Grm.
After volatilisation of the protochloride, carbonaceous matter	0.030
After combustion in air and reduction (by hydrogen), a graphitic residue	0.013

Carbon burned in air	0'017*
After combustion in oxygen and reduction, } greyish white residue of silica .. . }	0'005
Carbon burned in oxygen	0'008
Therefore 1 grm. of steel contains:—	
Combined carbon	0'0113
Graphite	0'0054

(2.) Five grms. of the same steel have been treated with chlorhydric acid. When the metal is dissolved the liquid has been boiled for a few minutes, the insoluble residue has been collected upon a plug of asbestos placed in the neck of a funnel, washed with boiling hot water, dried, and next heated to redness in a current of hydrogen gas.

The remaining residue weighed	Grm. 0'058
A whitish residue after burning in oxygen .. .	0'025
Graphite burned	0'033
For 1 grm. of steel:—	
Graphite	0'0066
Estimation according to 1.	0'0054
Difference	0'0012

1 grm. of steel has yielded:—

Silica according to 1	0'0034
Silica according to 2	0'0050

As regards the silica I ought to observe that neither of the two methods answers the purpose of correct estimation of that substance, because a portion of the silica is dissolved.

White Cast-Iron of Ria (Pyrénées Orientales).

(1.) 1'5 grms. of this cast-iron treated with mercury yielded:—

Carbonaceous matter	Grm. 0'089
After combustion in air and reduction, } slightly grey-coloured residue of silica .. . }	0'028
Burned-off carbon	0'061
For 1 grm. of the cast-iron:—	
Carbon burnt off	0'0406
Silica	0'019†

(2.) Five grms. of the same cast-iron has been acted upon by hydrochloric acid. The hydrogen gas given off during this operation had a very fetid odour. The liquid containing the insoluble residue had been boiled, and, further, been treated as already mentioned above in the case of the steel similarly treated.

The greyish coloured residue after reduction weighed	Grm. 0'043
Weighed after being heated in oxygen and reduction	0'040

Graphite burned	0'003
-------------------------	-------

The remaining residue was silica-like, quite white, and disappeared when treated by fluorhydric acid. One grm. of this cast-iron yielded, therefore, by this process:—

Graphite	Grm. 0'0006
------------------	----------------

The quantity of combined carbon which has disappeared during the dissolution amounts to 0'203 grm.

Grey Hot-blast Cast-Iron from Ria (Pyrénées Orientales).

(1.) Treated with bichloride of mercury 1'5 grms. of this metal yielded:—

* Combined carbon.
† Since the mixing with the bichloride of mercury has been performed in a glass mortar, there is a chance of silica having thus been introduced.

Carbonaceous matter	Grm. 0'0645	For 1 grm. —
After combustion in air and reduction .. .	0'0540	—
Burnt-off carbon = combined carbon	0'0105	0'0070
After combustion in oxygen and } reduction, white silica left .. . }	0'0050	0'0033
Burnt-off graphite	0'0490	0'0327

(2.) Five grms. of the same cast-iron treated with hydrochloric acid left a black-coloured residue, which, after having been treated as mentioned above, weighed:—

After combustion in oxygen, white silica left .. .	Grm. 0'257
Graphite burnt off	0'152
This amounts for 1 grm. of cast-iron to:—	
Graphite	0'0304
Silica	0'010

As already stated above, neither the treatment with bichloride of mercury nor with hydrochloric acid gives proper results for the quantitative estimation of the silica. When the Ria cast-iron is acted upon by *aqua regia*, and the process so conducted as to render all the silica insoluble in weak acid, 1 grm. of the metal yielded 0'0234 grm. of silica, equal to 0'0111 grm. of silicium. When grey cast-iron is dissolved in chlorhydric acid it is very probable that silicium is converted into silica, for I have found that when artificially-prepared siliciuret of iron is treated with an acid, silica only is obtained, partly in soluble, partly in insoluble, condition. If the carbonaceous residues above mentioned had contained a siliciuret or protoxide of silicium, the weight of the substances determined would have become greater than the quantity of matter submitted to combustion in consequence of the absorption of oxygen by the silicium. The results of these experiments are:— (1) When a carburetted iron is dissolved in chlorhydric acid, the total quantity of the carbon combined with the metal is eliminated, while the free carbon remains mixed with the other substances insoluble in the acid. (2) Since the residue left by a grey cast-iron treated by hydrochloric acid, contains a portion of the silicium which was combined with the iron in the state of silica, that residue does not contain any graphitoid silicium nor protoxide of silicium; the estimation of the silica in the residue does not represent the whole of the silicium contained in the cast-iron, because a portion of the silica remains in the acid liquid. (3) That the process based upon the difference of combustibility of the combined carbon and graphite is sufficiently exact to estimate the two kinds of carbon obtained by the action of bichloride of mercury upon the carbonaceous residue of cast-iron or steel.—*Ann. de Chim. et Phys.*

NOTICES OF BOOKS.

Report of the Deputy Master of the Mint on European Mints. Ordered by the House of Commons to be printed, August 10th, 1870.

THIS report has been drawn up by the Deputy Master of the Mint, in obedience to an order of the Lords Commissioners of Her Majesty's Treasury, whereby that gentleman and two officers of the Mint were requested to make a careful inspection of the management and working of the principal Mints of Europe; that is to say, those established at Madrid, Milan (where the Mints of the kingdom of Italy are in process of concentration), Florence, Rome, Constantinople, Vienna, St. Petersburg, Stockholm, Copenhagen, Berlin, Utrecht, Brussels, and Paris. We shall only quote from the Deputy Master's Report the headings of the subjects treated of, viz., Administration,

Mint Buildings, Refining, Standard of Fineness, Remedy of Fineness, Brittle Gold, Silver Melting, Levot's Experiments, Method of Taking Assays, Waste, Sweep, Dies, Verification of Gold Monies, Verification of Silver Monies, Annealing and Blanching, Size of Moulds and Bars, Rolling, Adjusting, Cutting, Adjustment of Blanks, Weighing Blanks and Coins, Remedy of Weight, Marking, Coining Presses, Balances.

Our readers will readily perceive from this catalogue that many subjects are treated of which, however interesting in themselves as bearing upon the speciality of the requirements of those manufacturing establishments which are termed Mints, are of less interest to the chemist.

There are, however, added to the report two appendices, termed enclosures, written by the gentlemen who accompanied Mr. Fremantle, the Deputy Master, on his inspection tour, the first thereof being from Mr. W. Chandler Roberts, Chemist to the Royal Mint, the other from the hand of Mr. James Murdoch Napier. This second report bears almost entirely upon mechanical operations, and, although of high value, and evidencing in a high degree the author's eminent knowledge in this respect, we will not further allude to it here, but confine our quotations to those taken from Mr. Roberts's extensive and valuable report.

The points named for consideration in this report are—

"Refining. Gold alloys. Gold melting. Silver melting. Subsequent treatment of gold and silver (annealing of filets, annealing of blanks, and blanching). Loss. Treatment of residues or 'sweep.' Verification. Adjusting blanks. Dies. Bronze."

Under the head of Refining, the following information is given on brittle gold:—

"Immediately connected with this subject is the fact that gold frequently contains minute traces of lead, arsenic, antimony, and bismuth. These metals, even when present, to the 1-2000th part of the mass, render the gold brittle and totally unfit for coining, probably by enabling the alloy known as standard gold to assume a crystalline structure. I find that on the Continent, those countries which have an extensive gold currency are but little troubled with brittle gold. The reason is obvious; the impure metals are removed by refining, which forms, as I have stated, one of the ordinary operations of the Mint; and the utmost care is taken to conduct the process in an efficient manner. With regard to the direct treatment of brittle gold, it is needless to remind you that the experiments in the English Mint have proved the advisability of adopting Miller's process."

Since the melting of the valuable gold and silver alloys as used for coinage is an operation of great importance we quote in connection therewith the following:—

"Gold Melting.—I now proceed to the description of gold melting. The nature of the gold to be operated upon, and its degree of fineness, having been determined by assay, a simple calculation will give the amount of copper to be added to form standard gold.

"Crucibles.—The crucibles in which gold is melted were formerly of refractory clay, and this material is still retained in the Mints of France and Belgium. It has in England been superseded by a mixture of graphite and fire-clay, known as plumbago. The amount of gold melted in each crucible is, in the British Mint, from 100 to 108 lbs. (or 37·3 to 40·3 kilogrammes), and I find a similar quantity is operated upon in other European Mints, the exceptions being those of St. Petersburg, Paris, and Vienna, which usually melt a larger quantity. The admixture of the metals is a matter of extreme importance, and this is effected by means of a stirrer of the same material as the crucible, in the form of a rod flattened at the end, and often of a spiral form. The copper is in all cases protected from oxidation by placing charcoal in the crucible.

"Method of Pouring.—In the English Mint the crucible is removed from the furnace by means of circular tongs,

and the contents poured directly into moulds. In many European Mints it is the practice to transfer the melted alloy from the crucible to the moulds by means of iron ladles covered with clay.

"Mode of taking the Portion of Metal for Assay.—In England it is usual to cut the portion of metal to be assayed from the bottom of the solidified bar. In many continental Mints the portion of metal taken for the verification of the standard is removed by a small ladle from the crucible; and at Constantinople the sample is taken after half the alloy has been transferred to the moulds. The bars of standard gold for the coinage of sovereigns at the English Mint are 1·375 inches wide, 1 inch thick, and 24 inches long. In other European Mints, with the exception of that at St. Petersburg, bars are cast of much smaller dimensions, those in Berlin being only three sixteenths of an inch thick. I consider that this practice presents many advantages, but in this case I defer my remarks until treating of silver melting.

"Gold-melting Furnaces.—I have examined with care the furnaces employed for gold melting. That furnace is best in which the combustion of the fuel is most perfectly effected; indeed I had hoped to have met with gas furnaces, as I am of opinion that their introduction into the English Mint would be very advantageous, not only from their cleanliness, but from the fact that the temperature would be completely under control. At Milan it was stated that plans are in preparation for the construction of gas furnaces, and should the Mint be removed from its present site, the advisability of the employment of gas as fuel shall receive my earnest consideration. The furnaces employed in the English Mint for melting gold are 24 inches (0·61 metre) deep by 12 inches (0·305 metre) square. I do not consider that any change should be made in the general construction of the furnaces as at present in use in the British Mint, but with regard to minor details, I am of the opinion that the openings might be altered with advantage. It is also a question for consideration whether, if the furnace opening were on a level with the floor, the necessary manipulation would be attended by less inconvenience to the operators. This arrangement is adopted at Stockholm, where, however, the amount of gold melted is extremely small."

"Crucibles for Silver.—The crucible at present employed in England for silver melting is of wrought-iron, 12 inches (or 0·305 metre) in diameter, and capable of containing from 333 lbs. to 416 lbs. of metal. At Milan silver is melted in very thin wrought-iron crucibles, in which 1607·5 lbs. (600 kilogrammes) are acted upon at one operation. The iron is protected by a thin but coherent film of fire-clay. At Brussels the crucibles are also of wrought-iron, of 2679 lbs. (1000 kilogrammes) capacity. The Vienna, St. Petersburg, and Utrecht Mints employ crucibles of cast-iron, capable of containing from 1607 to 2143 lbs. (600 to 800 kilogrammes). Those of Madrid, Constantinople, Rome, and Berlin employ crucibles of graphite, the capacity varying from 535·8 to 2520·1 lbs. (200 to 944 kilogrammes), as at Constantinople. I have no hesitation in recommending that graphite crucibles should be employed in preference to iron. Iron crucibles invariably absorb portions of silver either in the scales of wrought-iron, or even in the actual cavities of cast-iron. Indeed the crucibles at Vienna often contain many pounds of silver, and this is recovered by dissolving the iron with acid residues from the refinery. One other objection is that the silver becomes contaminated with iron. Graphite crucibles permit of the total contents being poured into moulds, and this enables the accounts to be adjusted daily, a point of Mint administration the value of which cannot be over-rated."

"Graphite Crucibles.—Experiments have recently been instituted in the English Mint, upon silver melting in graphite crucibles, containing 143 lbs. (53·37 kilos.), and have been attended with excellent results. The silver is either directly poured into moulds, or transferred by means of iron ladles lined with clay. In England the

silver bars are one inch thick; whereas, as I have already stated with regard to gold, in most European Mints the bars are of much smaller dimensions. In most European Mints, before the silver alloy is cast into bars, the contents of the crucible are stirred, and a small quantity of the metal removed by a ladle lined with clay or (as at Utrecht) by a pair of forceps which open in the molten mass, and enclose a button of metal. This test piece is assayed by the volumetric method, a process which occupies from 15 to 20 minutes, and, as in most cases the amount of alloy operated upon is very considerable, there is no inconvenience in maintaining the contents of the crucible in a molten state until the assay is completed. The melter is thus enabled to adjust, if necessary, the relative proportions of the constituent metals. The portion of metal taken from the crucible represents the actual composition of the standard silver with far greater accuracy than a test piece cut from the end of the bar of the solidified alloy."

"Levol's Experiments.—In order to explain this, it is necessary for me to enter somewhat minutely into the consideration of an important series of experiments conducted in the Mint at Paris by Levol, on the remarkable molecular mobility of alloys, in virtue of which certain combinations of the constituents of a molten alloy become segregated from the mass, the homogeneous character of which is thereby destroyed. Thus, to take an extreme case, an alloy containing 77·33 per cent of silver, and 22·67 per cent of copper was cast in a cubical mould of 42 millimetres. A portion cut from the centre of the mass gave on assay 78·318 per cent of silver, while a portion cut from one of the angles was found to contain only 77·015 per cent of silver, showing a difference of 13·05 milliemes. Levol proved that it is only the alloy containing 71·893 per cent of silver and 28·107 per cent of copper which is absolutely homogeneous. It is interesting to note that there is, as far as I am aware, no monetary alloy having this composition; the nearest, the Swedish standard, containing 75·00 per cent of silver. He also finds that while the alloy containing 71·89 per cent of silver is homogeneous, in all alloys containing more silver than this amount the centre of the solidified mass is richer than the exterior; on the other hand, in alloys of fineness lower than 71·89, the centre contains less silver than the external portions. It is of great interest to observe the results of an experiment on a cubical mass of 42 millimetres, similar in composition to the British standard. The maximum difference between the centre and one edge was 9·95 per mille, while the mean variation between the composition of pieces taken from different parts of the mass was 2·96 per mille. Fortunately the gold-copper alloys employed in the British and other European Mints present a very slight variation in composition, due to molecular arrangement. I may remark that the copper in the standard gold alloy has a singular tendency to oxidise even to the centre of the mass, a phenomenon in which I cannot but think the actual occlusion of oxygen plays an important part.

"Without entering into further details, I would draw the following practical conclusions:—

"1. The molecular re-arrangement must take place during the solidification of the mass, and the thin bars, therefore, which are in use on the Continent possess a decided advantage over the thicker ones in use in the British Mint, from the fact that they are more rapidly cooled.

"2. The continental method of taking the portion of metal for assay should be adopted in the British Mint, the composition of the alloy being much more accurately represented by a portion from the recently stirred fluid mass, than a test piece cut from the end of a solidified bar.

"3. Although the defects due to the non-homogeneous character of the alloy are to some extent modified by rolling the bars, still the centre of a fillet of standard silver often differs by at least 2·3 per mille from the edges, and a five-franc piece, therefore, will

vary in composition in different parts of the coin, the centre being the richest; or if (as is the case with the shilling) two coins are cut in the width of a fillet, the portion containing most silver will be near one edge of each coin.

"In England the method of cutting a piece from a silver coin for assay may not give a correct result, as a segment, or even a strip cut through a coin, may fail to indicate its composition with absolute accuracy. M. Stas, the head of the Belgian Mint, introduced the following accurate method. Small cylindrical or square portions are punched from various parts of the coin, the number and exact position of such pieces having been determined for each denomination of coin by calculations founded on an elaborate series of assays. I am indebted to M. Arthur Nyst, assayer of the Belgian Mint, for the results of experiments on the coins of that country."

The subjects of loss, treatment of sweep, and verification, being of considerable interest to chemists are quoted at length.

"Loss.—The metallurgical treatment of the precious metals is attended with unavoidable loss.

"In the English Mint the amount of loss on gold melting is considered to be 0·173 per mille, or one grain on the Troy pound. The apparent loss on silver melting under the new arrangements of the melting house is two grains on the Troy pound, or 0·346 per mille, much of the metal being recoverable from sweep. I have experienced great difficulty in obtaining accurate information with regard to the amount of loss that accrues during the manipulation of gold and silver in various European Mints. The following details were furnished to me:—

"In Mint A there is allowance of one per mille for loss on gold and 2½ for silver.

"In Mint B, a loss of one per mille for gold was considered to be a low estimate.

"In Mint C, the average loss was 0·7 per mille for gold, and 2½ for silver.

"In Mint D, the loss on gold was stated to vary from 0·2 to 0·4 per mille.

"The officers of the English Mint consider that the loss on the gold coinage will, for the future, certainly not exceed £200 on a coinage of one million, or 0·2 per mille.

"Cause of Loss.—The loss which arises from melting gold may be caused by volatilisation in combination with copper or other more volatile metals. I have stated above that the loss on gold melting has been found to be 0·173 per mille; but it has been experimentally proved by melting ingots, that there is a loss of 0·054 per mille due to foreign matters, weighed as alloy before the fusion. The precious metal actually volatilised may be arrested by condensation. This point has received much attention in the Roman Mint, where the flues of the gold-melting furnaces have been placed in communication with condensing chambers of simple construction, the adoption of which has been attended with very satisfactory results.

"I have already alluded, under the head of blanching, to a source of loss on melting worn coins. I now beg to call your attention to a point of much interest, experimentally developed by Dr. van Riemsdijk, who finds that the silver coins of five countries contain oxide of copper, in amounts varying from 0·3 to 2 per mille. On remelting old coin and scissel, there is a loss in weight, often of as much as 0·25 per mille, due to the reduction of oxide of copper to metallic copper by the charcoal under which the alloy is melted. Although I have no accurate information with regard to the loss on gold coins and scissel, still I am convinced that, with the present methods of annealing practised in the British Mint, the amount of loss arising from the above cause must be very sensible. It is true that the loss in weight is attended by a corresponding elevation of standard, but it nevertheless remains a distinct element of 'waste.'

"Treatment of 'Sweep.'—Under the term 'sweep' is comprised dust collected from the floors, ashes, dust from

flues, scrapings from crucibles, and residues generally which are likely to contain precious metal. At present it is the practice in the Mint in this country to grind the old crucibles, and to sift the product with the rest of the sweep through a sieve of 400 meshes to the square inch, the finer portions being sold to the highest bidder. In most European Mints the precious metal is extracted from the residues by the amalgamation process. I propose to make experiments with Mr. Crookes's sodium amalgamation process. I am not prepared to state that the extraction of the precious metal from a comparatively small quantity of sweep would be a source of actual profit, but I recommend that the operation should be undertaken by the Mint itself; for, as the gold and silver would be recovered in the metallic state, any deficiency would be absolute loss, and the amount of such loss would afford an intelligible indication of the degree of perfection attained in the conduct of the various operations.

Verification, or Assaying.—The method of gold assaying at the Mint in this country is identical with the process agreed upon at the Mint conference held at Vienna in 1857, and it is not possible to suggest any improvement in this respect, the excellent platinum apparatus of Messrs. Johnson and Matthey having been recently introduced into the establishment. In England, muffles heated with anthracite are employed, while at Berlin solid fuel is replaced by gas. I have no practical experience of muffles heated by gas, but the advocates of the method consider the temperature to be more completely under control.

"The method of silver assaying by cupellation is still employed in the British Mint, and, before proceeding to consider the practice of other European Mints, I may state that the chief objection to the method is the number of 'check assays' on standards of known composition rendered necessary by the variability of the temperature during the operation. In all other Mints the silver assay by cupellation has been superseded by the volumetrical method devised by Gay Lussac. The results are not accurate if the alloy contains mercury, as this metal interferes with the reaction. The process cannot be conveniently applied to silver alloys the composition of which is not approximately known, but this objection does not apply to the practice at the Mint, as trade assay reports are in all cases furnished with the ingots. The usual mode of conducting the volumetrical process is attended by certain errors arising from the solubility of the chloride of silver in the solution employed as a precipitant, and from the liberation of chlorine by the conversion of chloride of silver into subchloride by the action of light. These points have been investigated by M. Stas, and after a research detailed with the elaborate care so characteristic of his work, he finds extreme accuracy may be attained by substituting hydrobromic acid for the hydrochloric acid or chloride of sodium ordinarily employed. One great advantage of the modification of the process consists in the last traces of the silver being rapidly precipitated, and more easily distinguished than is the case with chloride of silver. Indeed, by employing an extremely accurate drop apparatus, the possibility is asserted of distinguishing the precipitate produced by a single drop of the decimal solution, or, in other words, the presence of the half of one-tenth of a milligramme (0.00005 grm.) of silver. The decomposing action of light is avoided in the Mints of Utrecht and Brussels by means of windows of yellow glass. I therefore suggest that experiments should be made in the Mint, to test side by side the cupellation and volumetrical methods, and that at the same time the manipulatory precautions suggested by M. Stas should be adopted.

"There is one other method of assaying practised in India; it consists in weighing the precipitated chloride of silver. The results obtained are very accurate, but the process entails much labour and delay, and I am not aware of its having been adopted in any European Mint."

While we have thus largely quoted from this excellent Parliamentary paper, we advise those of our readers who may be inclined to study this subject to read the whole of these fifty pages, which are obtainable for the very moderate sum of 3s.

The authors unanimously bear testimony to the very courteous and polite reception accorded to them everywhere on the Continent.

CORRESPONDENCE.

MAGNETISM AND DIAMAGNETISM.

To the Editor of the Chemical News.

It may interest some of your readers if I mention an experiment I tried the other day, revealing a fact which I have not seen mentioned elsewhere; more especially as it bears on an important magnetic law.

I took two magnets of about equal weight and power, and compared the attraction they had for one another with that which each had for a piece of soft iron. I found that, when in contact, the attraction for each other was the same as that of either for the soft iron; but at a short distance the former was double of the latter. The question which this result bears upon is this—when one pole of a magnet is in contact with a piece of iron or steel, does it produce in it a pole of an opposite name, or only of the same name? At a short distance, there is no doubt that it produces, in the part nearest itself, a pole of an opposite name, and that, as the distance diminishes, the two neutral lines, one between the magnet and the iron and the other in the iron itself, draw nearer and nearer to the point of contact. When there is actual contact, do these neutral lines vanish? All our text-books assume the negative. Du Moncel, in 1858, asserted that this was a mistake; and when there is actual contact, he declares there is no trace of any neutral line or of a pole of opposite name to the pole of the magnet. From such experiments as I have been able to try, I should say that if the pole of the magnet and the end of the piece of iron be exactly the same size, and perfectly ground so as to come into very close contact, the neutral lines disappear; but where this is not the case, the neutral lines disappear only at those particular points which are in actual contact, and that in those which are at a short distance there is a real double polarity. The experiment is very difficult to try; for if steel-filings be used, which is the simplest plan, it is almost impossible to prevent some particles from springing between the magnet and iron and so preventing perfect contact; and if we make an examination with a steel needle, the superior attraction of the magnet gives an appearance of repulsion between the needle and the points of the iron which are near to the magnet. But I think this appearance is deceptive; for the nearer the end of the needle is brought the less the repulsion, and when in contact there is an attraction; but again, this is sometimes produced by the reversal of the magnetism of the needle. Of course a single grain of dust of any kind between the magnet and the iron vitiates the experiment. At any rate, the little pictures given in our text-books (take, for instance, Ganot's "Physics," and Watts's "Chemical Dictionary") are drawn from mere fancy, and give an entirely erroneous idea of the facts as they are in nature.

While I am on this subject, let me observe that all the phenomena of diamagnetism, so-called, are perfectly explicable on old and well-known principles, without introducing any new property of matter. The distinction between magnetic and non-magnetic bodies, or rather between bodies more or less magnetic, is well known. Now when a body of small or no magnetic power is placed between the poles of a strong electro-magnetic, if it approaches either pole a voltaic current must be produced by this approach, parallel to and in an opposite direction to

the currents circulating round the pole of the magnet, and, therefore, a repulsion takes place. At the same time, as it was receding from the opposite pole, a current was formed parallel to and in the same direction as that circulating round this second pole, and therefore attraction takes place. Therefore, if the body, placed ever so little equatorially, approaches either pole, a current is formed, passing in a circuit round the length of the body, repelling it from this pole and attracting it to the other. These forces are in equilibrium only when the body stands equatorially at equal distances from each pole. In crystalline bodies the conducting power in different directions is modified by the axes and cleavage of the crystal. Hence these bodies comport themselves differently from non-crystalline bodies. *And here lies the whole mystery of diamagnetism.* When the specific conductivity of a body exceeds its specific magnetic power, it is diamagnetic; when otherwise, magnetic.

As it is very desirable to simplify, as much as possible, and diminish the number of natural laws, this simple and adequate explanation of the phenomena, which I have never seen given elsewhere, seems not unimportant.—I am, &c.,

H. HIGHTON.

Putney, December 22nd, 1870.

PS. In order to explain quite thoroughly from first to last the action of *diamagnetism* we must go a little deeper. Suppose any conducting body placed between the poles of an electro-magnet; the circuit is then closed; what is the consequence? According to well-known laws, two temporary currents are produced along the two longitudinal surfaces of the conductor which are nearest the poles of the magnet, both currents moving in the same direction, and both repelling the conductor from the poles of the magnet. These currents would form a circuit by returning along the interior longitudinal axis of the conductor. The conductor thus repelled from each pole takes up its equatorial position between the poles of the magnet at an equal distance from each; and is then kept there by the action described above, which prevents it approaching either pole. Let me add that all currents act more or less in pulsations; that, as each pulsation swells, currents are produced, repelling any body from each pole; as each decreases, currents are produced, attracting to each pole equally; thus, again, the equatorial position is the only position of equilibrium.—H. H.

SOLUBILITY OF TIN IN NITRIC ACID.

To the Editor of the Chemical News.

SIR,—Nearly eleven years ago, I observed that metallic tin was soluble in moderately dilute nitric acid at or near the freezing-point of water, and that this solution appeared to decompose with production of metastannic acid at temperatures above 41° F., or even at a lower degree if exposed to bright light.

I spoke of this tin solution in the year 1860, to my friend the late Mr. Frank B. Fowler, but he then expressed himself as having heard of the fact being published previously. Mr. Fowler afterwards invited me to go and see "some crystals obtained *in vacuo* from our tin solution," but his illness upset the arrangement.—I am, &c.,

WENTWORTH L. SCOTT.

THE SPECTROSCOPE IN WATER-ANALYSIS.

To the Editor of the Chemical News.

SIR,—In studying the best modes of rapidly detecting and localising the sewage contamination of a particular water-supply, I was led to devise a plan which, so far as I can tell at present, promises to be of great service. I will briefly illustrate its nature and use by an example.

On one side of a crowded court several cases of typhoid fever had been developed. The water used by the inhabitants of these houses was drawn from a rather shallow well, and was highly charged with various unoxidised compounds of nitrogen. It was suspected that the drain from a public urinal might be defective and have allowed egress of its contents into the well. This notion was confirmed by the quantity of common salt contained in the well-water, namely, seven times as much as that in the normal waters of the neighbourhood. But it received an absolute proof in the following novel manner. Two grammes of a *lithium* salt were introduced into the urinal. Two hours afterwards lithium was detected spectroscopically in a litre of the well-water before alluded to. A quantity of this water, ten times as large, showed no trace of lithium previously.

It is needless to point out the wide adaptability of this method to the detection of the particular source or sources of contamination in a water. Other metallic salts might be used, but those of lithium commend themselves on account of their harmlessness and ease of detection. They do not seem, moreover, to be much absorbed by most soils and gravels, and so are not stopped in their way to the wells.

Further experiments in the direction indicated in this brief note are in progress.—I am, &c.,

A. H. CHURCH.

Royal Agricultural College, Cirencester.
December 22, 1870.

MISCELLANEOUS.

University of London.—The following is a list of the Candidates who have passed the recent examination:—*Second B.Sc. Examination (Examination for Honours).*—Chemistry.—First Class. Robert Routledge (disqualified by age for Scholarship), Owen's College. Henry Newell Martin, Christ's, Cambridge, and University College, London. Second Class. Frank Clowes, College of Chemistry and private study.

Glasgow Philosophical Society (Chemical Section).—A meeting was held in the Society's rooms, Corporation Buildings, on Monday evening, the 5th inst., at eight o'clock. W. R. Hutton, Esq., in the chair. Dr. Wallace, F.R.S.E., President of the Section, and Gas Examiner for the City of Glasgow, delivered a lecture "On the Illuminating Power and Impurities of Coal-Gas." At the following meeting, held on the evening of the 19th inst., Mr. Robert R. Tatlock, F.R.S.E., read a paper "On Some Sources of Error in Volumetric Analysis," an abstract of which will appear in our next.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

The American Journal of Science and Arts, No. 150, November, 1870.

This number opens with the announcement that a third series will be commenced on the 1st of January, 1871. This series will be issued in monthly numbers of seventy-six pages, making two volumes a year of 456 pages each. Subscription for the year, 6 dollars or 50 cents a number.

Examination of the Bessemer Flame with Coloured Glasses and with the Spectroscope.—J. M. Silliman.—This important paper is reproduced *in extenso*.

A Simple Method of Measuring Electrical Conductivities by means of Two Equal and Opposed Magneto-Electric Currents or Waves.—Dr. A. M. Mayer.—This paper is illustrated with a series of woodcuts, and therefore is not well suited for abstraction.

Account of the Fall of a Meteoric Stone in Stewart County, Georgia, U.S.—Dr. J. E. Willet.—It appears, from the detailed account given in this paper, that on October 6, 1860, about 11:30 a.m., a meteoric fell from the sky, which was perfectly clear and cloudless at the time. The fall of the stone was attended by a very strong explosion. The stone was recovered almost immediately after it reached the earth; it gave off a peculiar odour; weighed 12½ ozs.; its colour within very like light-coloured granite; externally, it was covered with a smooth, almost black-coloured shell, a little thicker than common letter-paper; its shape was an irregular, seven-sided figure, its longest side being about 2½ inches long.

Description and Analysis of a Meteoric Stone that Fell in Stewart County, Georgia, U.S., on the 6th of October, 1860.—J. Lawrence Smith.—The author, on more closely investigating the stone alluded to in the foregoing paragraph, found its specific gravity to be 3.65. The fractured surface has a greyish aspect, and, when examined with a magnifying glass, exhibits numerous greenish globules, with a whitish granular material between. Through the mass are dark particles consisting principally of nickeliferous iron, with some pyrites, and a few specks of chrome-iron. The nodules are sometimes 3 or more m.m. in diameter, and of an obscure, fibrous, crystalline structure; they have a dirty bottle-green colour, a greasy aspect when broken, and are more or less opaque. Some of these nodules were separated in a tolerably pure state, and amounted to 121 m.m. On analysis it was found to contain—Silica, 48.62; alumina, 8.05; protoxide of iron, 12.21; magnesia, 30.18;—total, 98.06. Nickeliferous iron constitutes about 7 per cent of the mass; and a portion thereof, separated in as pure a state as possible, yielded, on analysis—Iron, 86.92; nickel, 12.01; cobalt, 0.75. The part of the stone soluble in acid, amounting to 58.05 per cent, was found to consist, in 100 parts, of—Silica, 47.08; alumina, 0.32; protoxide of iron, 18.45; magnesia, 41.06. The portion insoluble in acid, amounting to 41.95 per cent, was found to consist, in 100 parts, of—Silica, 56.03; alumina, 5.89; protoxide of iron, 15.21; magnesia, 2.00; lime, 0.70; soda, with a little potassa and lithia, 2.97. The soluble part is olivine, while the insoluble is bronzite, with a little albite or oligoclase. Chrome-iron was detected by fusing some of the stony part of the meteorite with carbonate of soda and a little nitrate of potassa, and separating in the usual way; the quantity was quite minute. The composition of the stone, as made out, would be, in 100 parts—Nickeliferous iron, 7.0; magnetic pyrites, 6.10; bronzite or hornblende, olivine, albite or oligoclase, and chrome-iron, together, 86.90.

Some Practical Remarks on the Use of Flame-Heat in the Chemical Laboratory, Especially that from Burning Gas, without the Aid of a Blast.—J. Lawrence Smith.—This essay is full of practical value; but, as the woodcuts are absolutely required for the subject to be properly understood, we cannot give an abstract.

Connection between Terrestrial Temperature and Solar Spots.—C. Abbe.—A valuable contribution to our knowledge on this subject.

Oxycalcium Light, as Applied to Photo-Micrography.—Lieutenant-Colonel J. J. Woodward.

Farmer's Theorem Discussed.—F. E. Stimpson.—This paper, and the following—

Note on Mr. Stimpson's Paper on Farmer's Theorem.—B. Silliman.—Bear upon the paper "On the Relation between the Intensity of the Light Produced from the Combustion of Illuminating Gas and the Volume of Gas Consumed," written by the last-named author.

Determination of the Photometric Power of a Rich Gas by Dilution with a Poor Gas of Known Value: the "Method of Mixtures."—B. Silliman.—The conclusions arrived at by the eminent author as the result of a series of experiments made with great care at the Manhattan Gas Company's Works, New York, are—(1) That in all illuminating gas we have a substratum of non-luminous gas holding in solution a variable volume of luminous gas (olefines). (2) That, when a gas is too rich in illuminants to permit of accurate photometric admeasurement by the usual standards of intensity, it may be diluted, with a poor gas of known value and volume, to such a standard as is consistent with the accurate employment of the usual photometric apparatus, its true value being then calculated from known values employed.

The Hailstorm of the 20th of June, 1870.—Rev. M. C. Hovey.—An interesting description of this extraordinary phenomenon, as witnessed by the author at Northampton, Mass., U.S. The paper is illustrated with several woodcuts exhibiting the structure and shape of the hailstones.

Photograph of a Solar Prominence.—Prof. C. A. Young.

Geological Explorations in China.—Baron von Richtenhofen.—This paper is a letter to Professor J. D. Whitney, dated from Pekin, August 20th, 1869, and containing a series of interesting details relating to the geology of the Celestial Empire.

Chemistry of the Bessemer Process.—Lieut. C. E. Dutton, U.S.A.—Reserved for full reproduction.

Earthquake of the 20th of October, 1870.—The brief report of some observations made on this phenomenon, which occurred in a portion of the States and adjacent Canada territories.

Zeitschrift für Chemie von Beilstein, No. 18, 1870.

Volatile Acids Contained in Croton Oil.—A. Geuther and O. Frölich.—The authors saponified a large quantity of croton oil with a strong caustic soda lye. They removed the soap from the

mother liquor, and after having saturated this alkaline fluid with sulphuric acid in excess, submitted the resulting liquid to distillation in a copper vessel; the aqueous distillate was neutralised with soda, evaporated to a small bulk, and again treated with sulphuric acid in excess. The crude fatty acids thus obtained were rectified, and by this process four liquids of varying boiling-points were obtained, viz.: (a) boiling at from 115° to 160°; (b) at from 160° to 190°; (c) at from 190° to 205°; (d) at from 205° to 270°. The first portion of these fluids was found to contain butyric and acetic, but no propionic acids. In the second portion the authors expected to find crude crotonic acid, and also quartenylic acid, which boils at about 171.9°; but, as evidenced by the following results of organic elementary analysis—C₁₀H₁₆O₂, in 100 parts, 58.8 carbon; 9.8 hydrogen; 31.4 oxygen; and C₁₂H₂₀O₂, in 100 parts—carbon, 55.8; hydrogen, 7.0; oxygen, 37.2—these figures show that acids belonging to the oleic acid series are not present in this fluid. The third portion, which crystallises on cooling, was found to contain an acid resembling angelica acid, a solid substance exhibiting colourless rhombic-shaped crystals, fusing at 64°, boiling at 201°. This body has been called tiglic acid by the authors, for although its formula is the same as that of angelica acid, that acid is distinguished from the body here alluded to by its fusing and boiling points, which are respectively 45° and 190°. The authors further state that it is possible that this tiglic acid (the name is derived from croton-tiglium) is identical with the methylocrotonic acid of Dr. Frankland and Mr. Duppa (*Ann. Ch. Pharm.* 136, 10). This supposition is strengthened by the fact that the ethyl ether of the tiglic acid, C₁₀H₁₈O₂.C₂H₅, boils at the same temperature (156°), as found for the methylocrotonic acid ether by the *savants* just named, while the specific gravity also agrees (0.926 at 21°). The ethyl ether of tiglic acid, moreover, corresponds in its properties with those of the methyl crotonic ether, being a colourless insoluble fluid, transparent in water, exhibiting a peculiar aromatic smell. Tiglicinate of barium, C₁₀H₁₇O₂.Ba+3H₂O, a salt crystallising in a small acicular shape, readily soluble in water. Tiglicinate of silver, (C₁₀H₁₇O₂)₂Ag⁺, obtained by precipitating the solution of the baryta salt, is a white coloured crystalline powder, very little acted upon by the sunlight. The fourth portion of the fractional distillation was only obtained in small quantity, and was found to contain, as far as tests and analysis admit of certainty, capronic, or cenanthylic or pyroterebinic acid. The authors conclude that their researches on this subject entirely eclipse those of Dr. Schlippe, who has (*Ann. Ch. Pharm.* 105, 49) erroneously stated that the volatile acids of croton oil should contain crotonic acid, C₁₀H₁₆O₂, and angelica acid.

Some Derivatives Obtained from Normal Propyl Alcohol.—Dr. C. Schmidt.—The following compounds are treated of in this paper: Bromide of propyl, C₃H₇Br, boils at 71.5°; iodide of propyl, C₃H₇I, boils at from 100° to 102°; formic acid propyl ether, prepared by the reaction of formiate of soda upon the bromide of propyl, formula C₃H₇.CHO, boils at 74°; sulphocyanide of propyl, C₃H₇.S.CN, an oily, disagreeable smelling liquid, boiling at 163°, not belonging to mustard oil (essential) series. Propyl sulphuric acid yields a baryta salt. Formula: (C₃H₇.SO₄)₂.3H₂O; propylamine, C₃H₇.NH₂, a fluid boiling at from 78° to 80°. The hydrochloride of this base is a very hygroscopic salt; the platinum salt, (C₃H₇.NH₂.HCl)₂.PtCl₆, is bright yellow coloured; the sulphate, (C₃H₇.NH₂)₂.SO₄, crystallises difficultly; cyanide of propyl, C₃H₇.NC, boils at from 95° to 100°, and is a very fetid smelling liquid.

Bayerisches Industrie und Gewerbe Blatt, September and October, 1870.

Review of the Mining, Mineral, and Salt Production in the Kingdom of Bavaria for the year 1868.—A valuable statistical account of the mining and metallurgical industry of the country alluded to. The particulars extend not only to the salt production, but also to that of graphite, porcelain, clay, gypsum, emery, alum, pyrites, and other minerals.

Water Supplied to the Towns of Kaiserslautern, Zweibrücken, Amberg, Bamberg, Bayreuth, Hof, Fürth, Erlangen, Rothenburg-on-the-Tauber, Nördlingen, Memmingen, and Neuburg-on-the-Danube.—A. Wagner.—This exhaustive essay was made at the suggestion of the Bavarian Ministry for Trade and Public Works, and contains the following particulars about each of the towns above named, number of inhabitants, physical geography, geology of the soil upon which the towns are situated, hydrography, means and methods of supply of water, physical properties, and full analysis of the waters. The author taking as basis the quantity of total solid residue contained in 1 litre of each of the 64 samples of water, classifies the water into seven classes, the first containing from 0.0 to 0.3 grm. of total solid residue, and the last from 2.0 to more grms. Only 4.7 per cent of the waters analysed belong to the first class, while to classes 6 and 7 belong respectively 14 and 11 per cent, both of these kinds of water being considered unfit for use for domestic purposes. The contents of this paper are chiefly of local importance, but the researches prove the truth of the ancient maxim, *tales sunt aquae quales terrae per quas fluvii*.

Effect of Wind and Weather as Affecting the Draught of Chimneys.—Dr. T. Huber.

Gabbro Mass.—J. von Schwarz.—Under this name the author prepares a plastic mass, consisting of two-thirds of steatite (chiefly a silicate of magnesia), one-third of pottery clay, and 1-16th of soda. The steatite is first ground with water and afterwards intimately mixed with the other ingredients. In a semi-dry state this mixture may be turned on the lathe the same as wood, but is chiefly used for making an excellent kind of pottery ware. When intended to be used instead of wood the mass may be coloured with aniline or other colouring matters.

NOTES AND QUERIES.

Manufacture of Kelp.—(Reply to "A Student").—Consult Wagner's large work on "Chemical Technology," vol. v.; "Musparr's Dictionary," and "Ure's Dictionary of Arts, Manufactures, &c.," all of which you can inspect at the library of the Commissioners of Patents.

Aniline Colours.—(Reply to "Stainer").—Your best plan is to consult the work on the "Aniline Colours," edited by the Editor of this journal, and published by Messrs. Longmans and Co., and also Schützenberger's work referred to on p. 312, No. 578 of this paper. As regards the alumina it is, in all probability, the amorphous and gelatinous oxide of aluminium which is meant by Mr. Perkin. Tannic acid forms insoluble compounds (lakes) with several of the so-called aniline colours.

Turkey-Red.—(Reply to "Magenta").—Some years ago a brief account of some experiments made with aurine were published in our pages. By referring to these you will probably meet with what you want but Turkey-red is a misnomer, for it only applies to a speciality of madder-dyeing; the aurine colours are not fast, but very beautiful. Rosolic acid, when dissolved in alcohol or acetic acid, is precipitated from these solutions by water in the shape of a deep orange-red coloured flocculent precipitate, and with baryta and lime compounds it forms insoluble crimson-coloured combinations.

Separation of Tarry Matter from Gas-Water.—(Reply to "Gas Engineer").—If the gas liquor be first neutralised with oil of vitriol or other acid (by which an additional quantity of tarry matter held in solution by the alkaline ammoniacal compounds therein, will be set free), it should be agitated in suitable close vessels with successive small quantities of bisulphide of carbon, which can be drawn off and re-distilled with very trifling loss, the tarry products also being saved. If, on the contrary, it is essential that the gas liquor be treated before neutralisation, it must be agitated under similar circumstances with any light form of naphthol or commercial benzene. I recommend both methods, but especially the first-named, from practical experience.—WENTWORTH L. SCOTT.

MEETINGS FOR THE WEEK.

MONDAY, Jan. 2nd.—Medical, 8.

TUESDAY, 3rd.—Royal Institution, 3. Prof. Odling, on "Burning and Unburning." (Juvenile Lectures.)

THURSDAY, 5th.—Royal Institution, 3. Prof. Odling, on "Burning and Unburning." (Juvenile Lectures.)

FRIDAY, 6th.—Geologists' Association, 8.

SATURDAY, 7th.—Royal Institution, 3. Prof. Odling, on "Burning and Unburning." (Juvenile Lectures.)

TEXT-BOOKS OF SCIENCE.

Now ready, in small 8vo., price 3s. 6d. cloth,

Inorganic Chemistry. By William Allen MILLER, M.D., LL.D., F.R.S., late Professor of Chemistry in King's College, London.

Being the Third of the New Series of Elementary Works on Mechanical and Physical Science in course of publication, edited by Professor T. M. GOODEVE, M.A.

* * * The Prospectus of the Text-Books of Science, with the List of works published and in preparation in the Series, may be had of all Booksellers.

London: Longmans, Green, and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane Tower Street, E.C. who hold stock ready for delivery.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870—1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Challenge to the World.—The *Bristol Daily*

Times and Mirror, August 5th, has the following:—Messrs. J. C. Swan and Co., of 16, Queen's Square, in this city, have invented a pocket microscope, which is a marvel in all that such an instrument should be. It has great power, remarkable definition, and does not require focussing. The cheapness of the article will make it exceedingly popular when its merits are more widely known. It is called the "Bristol Microscope," and is a great credit to the inventor, as much for its extreme simplicity as its power.—The *Western Daily Press* says: The Bristol Microscope has a magnifying power of 20,000 times, &c., &c.—The *Western Daily Telegraph* says: The Bristol Microscope is the most compact and useful scientific instrument we have ever seen; it possesses extraordinary power, and is very easily managed, &c. The price of the Bristol Microscope is only 2s., or free by post, with printed directions, for 28 stamps.—Address, J. C. Swan and Co., Opticians, 16, Queen Square, Bristol.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Chloride of Calcium (Purified Muriate of Lime),

total insoluble impurities under $\frac{1}{2}$ per cent.
CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{2}$ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

Royal Polytechnic.—Novel and bona fide

Character of the CHRISTMAS HOLIDAY ENTERTAINMENTS.—PROFESSOR PEPPER ON THE WAR, AND THE DESTRUCTIVE IMPLEMENTS USED THEREAT.—MR. GEORGE GROSSMITH, jun., gives the prettified Fairy Tale, entitled THE YELLOW DWARF, every Evening: Mr. Suchet Champion the same in the Mornings, with Vocal Illustrations.—Engagement of the Original Warlock, Mr. J. BEAUMONT, for the WORLD OF MAGIC, and his Curious Slack Rope Automaton, Entertainment by Mr. E. D. DAVIES, Premier Ventiloquist, entitled THE FUNNIEST OF FUNNY FOLKS.—MADAME BOUSFIELD'S GRECIAN STATUARY in White Marble.—THE PRAEGER FAMILY.—New Ghost Entertainment.—A Machine-made Watch, and Christmas and Christmas Customs, by J. L. KING, Esq., at the ROYAL POLYTECHNIC.—Admission to the whole, One Shilling.

INDEX.

- ABBE, C.**, connection between terrestrial temperature and solar spots, 323
- Abel, F. A., F.R.S.**, committee on the chemical nature of cast-iron, 161
- Aberration**, minimum of prismatic, 227
- Absorption of light**, 240
- spectrum of fluid hyponitric acid**, 240
- Acetic acid**, anhydrous, bromated derivatives of, 70
phosphate of lime in, 178
vapour density of, 154, 202
- Acetyl-derivatives of ammonia**, 312
- Acid-oxalates of potassium, ammonium, and sodium**, 14
- Acids, volatile**, contained in croton oil, 323
- Aconite alkaloids**, 216
- Acoustical attraction and repulsion**, 71, 131
- Acoustics**, 96, 227
- Acridine**, 192
- Aeronautics**, abridgments of specifications relating to, 44
- Adalbert Iron Works**, description of, 240
- Ador, E.**, on phthalyl, 59
radical of phthalic acid, 108
and A. Oppenheim, sulphobenzoic acid, 213
- Agassiz, L.**, bottom of the Atlantic Ocean, 47
- Agoniada and agonidine**, 84
- Air of schoolrooms**, carbonic acid in, 83
oscillation of in pipes of different shape, 35
pollution by chemical works, 27, 37
specific heat of under pressure, 227
- Albumen**, 62, 190
compounds, 84
of eggs, properties of, 168
- Alcohol**, 71
and starch, 192
and water, density and freezing-point of mixtures of, 96
normal propylic, conversion of allyl-alcohol into, 226
derivatives obtained from, 323
specific gravity of, 191
- Aldehyd**, conversion of chloral into by inverse substitution, 58
polymeric modifications of, 47
- Aldehyd-collidine**, 202
- Alizarine**, 130, 168, 180
- "Alkali Act, 1863; Sixth Annual Report" (review)**, 165
- metals**, action of vapours of upon molten cast-iron, 48
trade of Lancashire, 161
- Alkalies in silicates**, 84, 96
contained in the mineral leucite, 13
- Alkaloids**, 192
in plants of the Boraginææ, 262
- Allain, M.**, manufacture of carbonate of baryta and artificially-made barytic stones, 72
- Allen, A. H.**, determination of ferrous oxide in substances insoluble in acids, 57
- Allen, J. F.**, alloys of copper, tin, zinc, and lead with manganese, 194
- Alloy known as "Tiers Argent,"** 225
of cobalt and manganese, 34
- Alloys**, analysis of, 48, 60
- Allyl alcohol**, conversion of into normal propylic alcohol, 226
chloride of and hypochlorous acid, 36
cyanide, 144
- Allylic alcohol**, 71
- Alsberg, M.**, bromonitro- and bromamido-benzol, and position the hydrogen of benzol occupies, 84, 144
- Alumina and magnesia**, circumstances which favour the simultaneous precipitation of by ammonia, 4
- Aluminium**, electro-thermic properties of, 70
hydrated chloride of as an antiseptic, 165
in batteries, 228
ethyl, 70
weights, 187
- Amagat, Dr.**, compressibility and expansion of gases, 34
- Amalgam-hydrogenium**, 96
- Ambrosine**, 71
- Amides**, action of phosgen on, 144
- Amido bases**, isomeric, from a hydrocarbon, 82
- Amido-sulpho-phenol**, 215
- Amido-toluylen-sulpho acids**, 214
- Ammonia**, acetyl derivatives of, 312
action of on chloro-propionic and iodo-propionic acid, 287
upon chlorides of thionyl and selenium, 226
and nickel, double chromate of protoxide of, 287
anhydrous liquid, the solvent power of, 217
gas, changes of colour of flowers in, 239
machine, 47
nitrate of, decomposition of, 168
oxalate of, carbonic and alcoholic fermentation of, 34
simultaneous precipitation of alumina and magnesia by, 4
- Ammoniacal salts in the human organism**, 21
- quantitative estimation of**, 21
- Ammonio-magnesium phosphate**, estimation of phosphoric acid as, 227
- Ammonium**, potassium, and sodium, composition of acid-oxalates of, 14
sulphocyanate of, 72
- Amygdalin and amygdalinic acid**, 83
- Amylic alcohol**, 106
- Analysis**, chemical, introduction of the principle of repetition into, 190
elementary, 153
of water of two mineral springs near Cairo, 144
quantitative, new method of, 275
- Analysts' fees**, 11
- Analytical processes**, new, 190, 229
- Andrian, F. von**, geological studies concerning the Orient, 202
- Aniline**, action of chloride of sulphur on, 59
black, dyeing, poisoning by, 191
dyes, colouring power, 130
or coal-tar colours, 17, 29, 40, 53, 64, 79, 92, 100, 312, 324
- Animal charcoal**, decolourising property of, 240
improvements in manufacture of, 118
kingdom, commensalism in, 120
- Anthracen**, 59, 83, 204, 216
orange, 166
derivatives, 37, 283
- Anthrachinon**, 130
behaviour of to nascent hydrogen, 166
- Antidote for snake poison**, 179
- Antimonic acid**, 58
- Antimonous sulphide**, precipitation of from boiling solutions, 190, 259
- Antimoniurets of copper, lead, nickel, silver, and iron**, 83
- Antimony oxide** of from Algeria, 58
- Antiseptic treatment of contagion**, 195
- Antiseptics**, 166
- Antozone and ozone**, 35
- Antwerp church tower**, latitude of, 119
- Aor, E.**, aldehyde-collidine, 202
- Appolt, T.**, coke from non-caking coals, 191
- Aqueous solutions of chemical compounds**, specific heat of, 154
- Arbutine**, 35
- Argènes of Paris**, 24
- Argostemma**, new species of, 71
- Aromatic glycol**, 202
hydrocarbons, 201
- Arsenates and phosphates**, 61
- Arsenic and arsenious acid**, ethers of, 96
detection of in sulphuric and hydrochloric acids, 214
metallic, method for purifying, 167
- Arseniurets of copper, lead, nickel, silver, and iron**, 83
- Arsines and phosphines**, action of chlorides of platinum, palladium, and gold upon, 58
- Arson, M.**, Montyon prize, 46
- Artesian wells**, 168
- Artificial light**, new, 20
stone and various kinds of silica, 195
- Artus, J.**, bleaching ivory, 48
- Arzberger, Dr.**, the electric clock, 155
- Asbolan**, 24
- Asphyxia by charcoal vapour**, 47
- Atacamite**, 261
- Atomic volumes of solid compounds**, 190
weights, 21
- Aurora**, spectrum of, 225
- Augite in minerals**, 96
- Ausset, M. D. D.**, death of, 72
- Avogadro law**, derivation of from mechanical theory of heat, 263
- Azobenzol-sulphuric acid**, 35
- Azotoluol**, 59
- Azoxybenzide**, action of pentabromide of phosphorus upon, 144
- BAEHR, G. F. W.**, results obtained by the mathematical study of the movements of the eye, 72
- Baeyer, A.**, aldehyde-collidine, 202
bases of the pyridine and chinolin series, 201
euxanthon and euxanthinic acid, 201
reduction of aromatic hydrocarbons by iodophosphonium, 201
and A. Emmerling, reduction of isatine to indigo blue, 59
- Baillie, J.**, and A. Cornu, estimation of the absolute value of the intensity of terrestrial magnetism, 21
- Balling, C. M.**, desilvering lead by zinc, 240
- Ballo, M.**, action of nitric acid upon toluidine, 155
naphthylamine, rosaniline, and brom-naphthaline, 130
- Bardy, C.**, preparation of organic bases for colouring matters, 180
- Barium chlorate**, preparation of, 209
platinate of, and hydrate of platinate acid, 47
- Barometer**, aneroid, for heights, 274
weighing or balance, for compensating for temperature, 154
- Barometrical oscillations**, Mariotte's theory, 143
- Barth, L.**, isomeric cresols, 83
products of conversion of phenol, 288
- Bathometer**, new and improved, 311
- Barringer, J.**, sorbinic acid and so-called para-sorbinic acid, 202
- Baryta carbonate of and barytic stones**, 72
- Basicity (basicität) of acids**, 59
- Batalin, A.**, action of light upon the tissues of some mono- and di-cotyledonous plants, 154
- Batteries**, galvanic, 69
- Battery**, electrical, 95
magnetic power of, 310
- Bauer, A.**, alloy of lead with platinum, 263
G., manufacture of steel types, 118
- Baumhauer, Dr. E. H. von**, etching, 96
specific gravity of alcohol and alcohol and water, 71, 191
- Béchamp, A.**, carbonic and alcoholic fermentation of acetate of soda and oxide of ammonia, 34
- Bequerel, Professor**, electric effects produced by contact of non-oxidisable metals with acids, neutral and saturated saline solutions, and on capillary affinity, 21

- Becquerel, Prof., new researches on electro-capillary action: formation of crystallised oxychloride of copper and other analogous compounds, 58
- A. C., and E. M., observations of the underground temperature in the Jardin des Plantes, at Paris, from 1864 to 1870, 58
